OFFICERS OF THE SECTIONS

SECTION OF MEDICINE

Chairman Francis C. Hall, Boston *vice chairman*, Laurence B Ellis,
 Boston, *secretary*, Allen S Johnson, Springfield

SECTION OF SURGERY

Chairman, George S Reynolds, Pittsfield *secretary*, Robert E. Gross,
 Boston **EXECUTIVE COMMITTEE** — John W Spellman Brookline Charles
 C Lund, Boston Langdon Parsons, Newton

SECTION OF PEDIATRICS

President, Lewis Webb Hill, Boston *secretary*, Gerald N Hoessel Boston
 and Cambridge **EXECUTIVE COMMITTEE** — Leroy T Stokes, Haverhill,
 Floyd R Smith, Pittsfield Hyman Green Boston

SECTION OF OBSTETRICS AND GYNECOLOGY

Chairman, Arthur T Hertig Boston and Winchester *vice-chair*
 James F Conway Brookline and Roslindale *secretary*, Dan
 McSweeney Milton

SECTION OF RADIOLOGY

Chairman Hugh F Hare, Boston and Newton *secretary*, Albert
 Moloney Boston and West Roxbury

SECTION OF PHYSIOTHERAPY

To be announced

SECTION OF DERMATOLOGY AND SYPHILOLOGY

Chairman, Austin W Cheever, Boston *secretary*, Maurice M Tolt
 Chelsea

SECTION OF ANESTHESIOLOGY

Chairman, Urban H Eversole Boston *secretary* Morris J Nichols
 Boston

OFFICERS OF THE DISTRICT MEDICAL SOCIETIES FOR 1947-1948

BARNSTABLE — *President*, Henry P Hopkins, Chatham *vice president*,
 Arthur J D'Elia Harwich Port *secretary*, Frederick Sanborn Barnstable,
treasurer, Frank Travers, Barnstable *librarian*, Carroll H Keane Chatham,
executive and public relations counselor, Paul P Henson, Hyannis

BERKSHIRE — *President* Modestino Criscitiello, Pittsfield *vice-president*,
 George S Reynolds, Pittsfield, *secretary*, Daniel N Beers, Pittsfield, *treasurer*,
 Theodore W Jones Pittsfield *legislative counselor* John Hughes, Pittsfield
public relations counselor, Patrick J Sullivan, Dalton

BRISTOL NORTH — *President*, Joseph V Chatigny, Taunton, *vice president*
 James H Brewster Attleboro *secretary*, William L Dawson, Taunton *treasur-*
er, Charles E Hoyce, Taunton, *executive counselor* Joseph L. Murphy,
 Taunton *legislative counselor* William M Stobbs, Attleboro *public relations*
counselor Milton L Johnson Attleboro

BRISTOL SOUTH — *President*, George W Blood, Fall River *vice-president*,
 Aubrey J Pothier New Bedford *secretary and treasurer*, James E Fell, Fall
 River *executive counselor* Richard B Butler, Fall River *legislative counselor*,
 Curtis C Tripp New Bedford *public relations counselor*, Harold E Perry
 New Bedford

ESSEX NORTH — *President* Lincoln C Peirce, Newburyport, *vice president*
 Robert E Bliss Amesbury *secretary and public relations counselor*, Harold R
 Kurth Methuen *treasurer* J Leroy Wood Methuen *executive counselor*,
 Rolf C Norris, Methuen *legislative counselor* Nicandro F DeCesare, Methuen

ESSEX SOUTH — *President*, Leonard F Box, Beverly *vice-president*,
 Alexander Kotarski, Peabody *secretary*, Henry D Stebbins, Marblehead
treasurer, Andrew Nichols 3rd Danvers *legislative counselor* Loring Grimes
 Swampscott *public relations counselor* Bernard Appel Lynn *executive coun-*
cilor, Walter G Phippen Salem

FRANKLIN — *President*, John B Temple, Shelburne Falls *vice-president*,
 Lawrence R Dame Greenfield, *secretary and treasurer* Harry L. Craft Ash
 field *public relations counselor* Howard M Kemp, Greenfield

HAMPDEN — *President*, Arthur F G Edgelow Springfield, *vice-president*
 Robert Hildreth Westfield *secretary and treasurer* George C Steele West
 Springfield *executive counselor* Archibald J Douglas Westfield *legislative*
counselor, Arthur Riordan, Indian Orchard, *public relations counselor*, Frederic
 Hagler Springfield

HAMPSHIRE — *President* John J Curran, Northampton, *vice-president*,
 Edward J Maxwell, Northampton *secretary and treasurer* F Mary P Snook,
 Worthington *librarian*, Abbie M O Keefe Northampton *executive counselor*,
 Henry A Tadgell Belchertown *legislative counselor*, Lawrence N Dargin
 Amherst *public relations counselor* Joseph R Hobbs Williamsburg

MIDDLESEX EAST — *President*, Daniel L Joyce Woburn *vice-presi-*
 Milton J Quinn Winchester *secretary*, Roy W Layton Melrose *treas-*
 Albert E Small Melrose *librarian*, Angelo L. Marietta Winchester *f*
lic relations counselor Milton J Quinn Winchester

MIDDLESEX NORTH — *President* C Stoyke Baker, Lowell *vice-presi-*
 James Y Rodger, Lowell, *secretary* Brendan D Leahy, Lowell *treasur-*
 Mason D Bryant, Lowell, *executive counselor* William M Collins Low
legislative counselor, A. Warren Stearns, Lowell *public relations coun-*
 Samuel Dubbins, Lowell

MIDDLESEX SOUTH — *President*, John F Casey, Allston, *vice presi-*
 Arthur M Jackson Everett *secretary*, Alexander A Levi Newton *treas-*
 Fabjan Packard Belmont, *orator*, Viado A Getting Belmont *execu-*
counselor, Harold G Giddings Newton *legislative counselor*, Kenneth
 Tillotson Belmont *public relations counselor* Ralph H Wells Lexington

NORFOLK — *President* Carl Bearse Newton *vice president* George
 Papen, Brookline *secretary* Basil E Barton, West Roxbury *treasurer* Er
 erick Reis Jamaica Plain, *executive counselor*, Charles J E. Kickham, Jam
 Plain *legislative counselor* Solomon L Skvirsky, Chestnut Hill, *public relat-*
counselor, Dean S Luce Canton

NORFOLK SOUTH — *President* Robert L. Cook, Quincy *vice-presi-*
 George D Dalton, Wollaston *secretary and librarian*, Ebenezer K Jeak
 Braintree *treasurer* Francis G King North Quincy, *executive coun-*
 Fred A Bartlett Wollaston *legislative counselor*, David L Belding High
public relations counselor Henry A Robinson Hingham

PLYMOUTH — *President* Ralph C McLeod Brockton *vice-presi-*
 Sterling A McLean Middleboro *secretary* Samuel Gale Brockton, *treasur-*
 Alton L Hurlburt East Bridgewater *librarian* John H Weller Bridgewat
executive counselor George A Moore Brockton, *legislative counselor* Alfred
 Duncombe Brockton *public-relations counselor* Charles D McCann, Brock

SUFFOLK — *President* Charles C Lund Boston *vice president* Hollis
 Albright, Boston *secretary* Charles G Shedd, Boston, *treasurer* Richard
 Eustis Boston, *executive counselor* Alexander J. A Campbell, Boston, *legi-*
sative counselor, William E Browne Boston *public-relations counselor* How
 F Root, Boston

WORCESTER — *President* Frank B Carr, Worcester, *vice president*, Jo
 J Dumphy Worcester *secretary* Julius J Tegelsberg Worcester *treasur-*
 Arthur D Ward Worcester *librarian*, John M Fallon Worcester *execu-*
counselor, Bancroft C. Wheeler Worcester *legislative counselor* George
 Dunlop Worcester *public relations counselor* Nicholas S Scarcello Worces

WORCESTER NORTH — *President* Jesse C. Hales Gardner, *vice presi-*
 Donald B Cheetham Athol *secretary*, James G Simmons Fitchburg *treasur-*
 urer, Frederick H Thompson, Jr, Fitchburg *executive and legislative coun-*
 John J Curley Leominster *public-relations counselor*, James V McHaf
 Leominster

COARCTATION OF THE AORTA

A Review and a Report of a Case

EDWARD D MAIRE, M D *

DETROIT, MICHIGAN

IN 1933 Sir Thomas Lewis¹ expressed the following opinion: "So much has been written about coarctation of the aorta that new records of cases can have little value unless they reveal new features of interest and importance to the study of the condition." With this sentence he began a paper that—for completeness in both theoretical and practical considerations, as well as in the presentation of the anatomic, physiologic and clinical features—can well be used as a model by present day authors on any medical subject.

The purpose of this paper is to report a case of coarctation of the aorta in a bombardier, to re-emphasize much of what Sir Thomas Lewis had to say about the subject, to abstract several points brought out by a few of the earlier and later writers, to exhort physicians to search for the condition oftener, to discuss the prognosis in coarctation of the aorta, particularly as the problem pertains to civil, military and Veterans Administration practice and, what is perhaps most important, to report on the recent advances in the surgical treatment of aortic atresia.

ANATOMY

Coarctation of the aorta is generally classified into two anatomic groups, both of which are located preponderantly in the distal portions of the arch. The first form, which is generally known as the infantile type, is characterized by a generalized narrowing of the arch in its distal portion, extending from the origin of the left subclavian artery to the region of insertion of the ductus arteriosus. Clinically, this form is rare, accounting for 7 of 183 cases cited in one series,² and is so frequently accompanied by other major developmental anomalies, such as a bilocular or trilocular heart, a transposition of the arterial trunks and pulmonary atresia,³ that death occurs in infancy. The adult type is characterized by an abrupt narrowing—

sometimes to the extent of obliteration—of the aorta in the proximity of the insertion of the ligamentum arteriosum (Fig 1), it should not be classed as a rarity in clinical medicine. Blackford⁴ found an incidence of 44 cases in 68,300 cases at autopsy (1 1550) reported by various observers. The incidence is 3 1 in favor of men. That the patient with the adult type of coarctation lives—and, in fact, may physically prosper—for years in spite of so marked a defect is probably due to the responsiveness of other vessels in forming a collateral circulation, as well as to the fact that the associated developmental anomalies, if any, are less serious than those found in the infantile group. These defects, which are comparatively minor,² fall into two main groups. The first comprises anomalies of the heart and great vessels, including bicuspid aortic valve, anomalous origin of the arteries of the aortic arch, persistent left superior vena cava, aortic septal defects and subaortic stenosis, and the second, anomalies of the body at large, including hypospadias, absence of the left kidney, vertical position of the stomach, horseshoe kidney, diaphragmatic hernia, subluxation of the joints, slight Mongolianism, ichthyosis, pigeon breast and congenital cerebral-vessel aneurysm. Because of the obvious value of a search for these associated anomalies these lists are taken directly from an article by Hamilton and Abbott.² These authors state that the defects of the heart and great vessels are so frequent as to be almost a part of the complex. Bauer and Iverson⁴ described a case accompanied by complete double pelvis and ureter and an accessory renal artery on the left. That many developmental anomalies exist in aortic coarctation may be fully expected with a defect that is probably an embryologic deviation itself.

PHYSIOLOGIC CIRCULATORY CHANGES

Marked anatomic changes of the various branches of the aorta, all designed to establish a satisfactory circulation to the organs normally supplied by

*Chief, Department of Medicine, St. Joseph & Mercy Hospital

arteries branching from the aorta distal to the coarctation, develop with the demands of the body. The formation of this collateral circulation,² although not uniform, takes place mainly through the

intrascapular and subscapular arteries, all of which arise from branches of the aortic arch and thus proximal to the stenosis, and the second intercostal artery, blood passes through the internal mammary

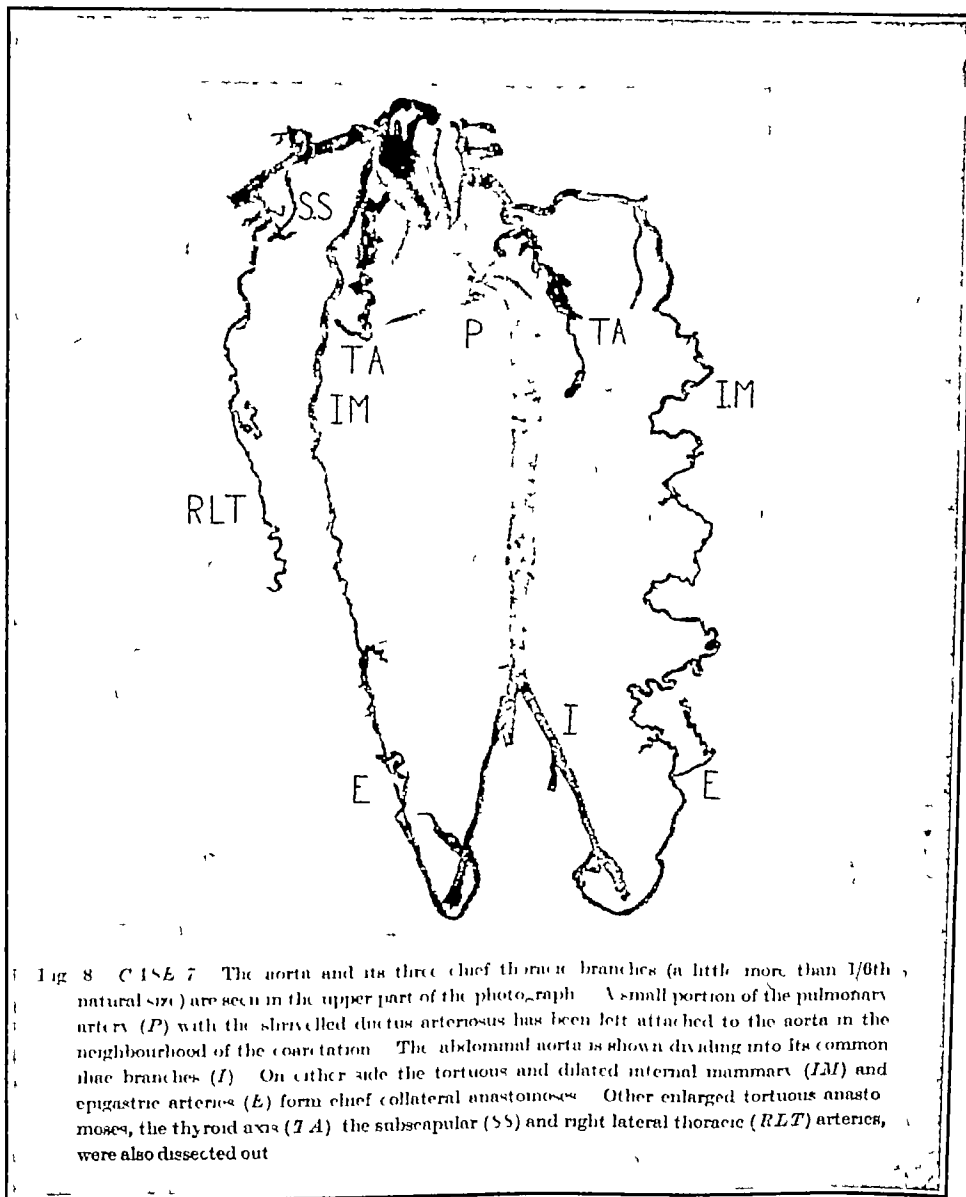

FIGURE 1

This illustration, taken from Lewis,¹ illustrates the formation of the collateral circulation.

following developments: an anastomosis between the superior intercostal artery, arising from the subclavian, and the first aortic intercostal artery, which comes from a point just distal to the stenosis; an anastomosis between the posterior scapular,

branch of the subclavian to the descending aorta via the epigastric and iliac arteries (Fig 1). This collateral circulation, when well developed, supplies sufficient blood to the aorta distal to the coarctation so that, even should obliteration be complete, cir-

culuation of blood to the viscera of the abdomen and to the musculature of the lower extremities is frequently satisfactory. It has been shown that the blood vessels of the skin and muscles of the lower extremities are normal in comparison to those of the upper extremities and regions supplied by blood vessels proximal to the coarctation.⁵

The blood flow appears not to be uniformly affected, since some authors have discovered a

nocturnal cramps in the legs of 2 patients over forty years of age, and they concluded that the velocity flow in the larger arteries of the legs was reduced and the femoral pulse delayed as much as 0.15 second after the radial pulse. They found the blood oxygen in the lower extremities not diminished in a patient at rest. Stewart and Bailey⁹ found the arm-to-perineum and arm-to-leg circulation times prolonged in most of 14 cases. The aorta and all

FIGURE 2

A roentgenogram, taken from Lewis¹ illustrates sulcation of the inferior borders of the posterior portions of the ribs

decrease in renal flow⁶ and others an increase in the peripheral vessels.⁷ In a careful study of 12 cases by Stewart and his associates,⁷ the circulation time was found to be prolonged in some, normal in a few and decreased in others. They point out that the prolongation of the circulation time was effected by the devious collateral routes of the blood and that the normal or decreased times were produced by a well developed increase in the cardiac output that overcame this handicap, the skin and rectal temperatures were also increased as a rule. Blumgart et al.⁸ noted intermittent claudication and

the arteries arising from it proximal to the constriction undergo absolute dilatation,* and the left ventricle usually hypertrophies slightly, especially if high blood pressure be present, in well marked, uncomplicated cases of coarctation. Lewis¹ believed that this dilatation produced a volume in the arterial bed proximal to the coarctated region about equal to the arterial volume in the normal person without

*Measurement of the degree of dilatation of the aortic branches would be tedious and technically difficult. To measure merely the mouths of the great branches at the aorta as suggested by some⁴ is entirely inadequate for the elasticity and the caliber of the lumen along the entire course of these vessels must be calculated to ascertain the complete degree of dilatation.¹

stenosis, in other words, the increased resistance to the blood leaving the left ventricle, expected on the contraction of that organ because of aortic constriction, is compensated for by dilatation of the proximal aorta and its branches. This answers part of the query of why a heart working against an increased tension is often little enlarged but leaves unanswered the question of the cause of the hypertension.

In view of one of the modern concepts of the etiology of hypertension, reduced blood flow to the

diastolic pressure in the femoral artery was almost the same as that in the brachial artery. This suggested that the peripheral resistance is increased in the legs as well as in the arms.

EMBRYOLOGY

Embryologists are probably quite close to the explanation of the development of coarctation of the adult type. Brunner¹¹ asserted that the tissue of the ductus arteriosus at its junction with the

FIGURE 3

This roentgenogram, taken from Lewis,² is a left oblique view that illustrates the extension of the great-vessel silhouette high into the neck and an area of abnormal clearness posterior to the aortic column.

kidney, it is emphasized that the volume flow and circulation time to this organ may or may not be normal, although some believe that adverse changes have been demonstrated.⁶ Using direct puncture methods for determining the blood pressures in the brachial and femoral arteries in a case of coarctation, Steele and Cohn¹⁰ found that the systolic pressure in the brachial artery was higher but that the

aorta, which at birth naturally becomes completely stenosed, anomalously incorporates the contiguous portion of the aorta in this obliterating action. The primitive fourth arch (the aorta) falls prey to the obliterating overaction of the primitive sixth arch (the ductus). Some authors point out that the ligamentum arteriosum exerts a tent-rope-like tugging on the aorta at the junction of the two, causing

a kinking of the aorta that produces a stenosis. Just what the process is in the extremely rare cases of coarctation situated away from the region of the ductus insertion is difficult to conjecture. One case is cited in which the stenosis occurred proximal to the origin of the left subclavian artery,² and record has been made of a stenosis in the abdominal aorta.¹² Such locations lend support to the theory of Reynaud and Rokitsansky, who believed that coarctation

conspicuous by their absence. This is especially true, in the majority of cases, in the early decades of life — that is, until the reserve of nature's bounty is consumed. Patients rarely present complaints until early adulthood and usually reach the third and fourth decades before consulting a physician, in spite of the fact that the expectancy of life is much shortened. Abbott¹³ reported that in 74 per cent of 200 cases the patients died during or before

FIGURE 4

A roentgenogram, taken from Lewis,¹ showing the area of abnormal "clearness" posterior to the aortic column in the right oblique view

was due to embryonic maldevelopment of the descending limbs of the primitive left aorta

SYMPTOMS

Although the adult type of coarctation of the aorta is present at or soon after birth (if Skoda's theory of postnatal paulocardia is correct) and persists throughout life, — whose span it definitely shortens as pointed out below, — the symptoms are

the fortieth year. Lewis's¹ report included 8 soldiers, all of whom had led vigorous lives in childhood and who had done well during rigorous training or combat in World War I. One of his patients first presenting symptoms of fatigability and breathlessness on exertion at the age of nineteen years had, in boyhood, walked several miles each day to school, performed physical drill and played with his school fellows such games as cricket, football and leapfrog

without difficulty, after returning home he had played in the streets till late, going to bed at 10 or 11 o'clock. He had frequently taken part in races of several miles' length and had held his own. For five years he had worked with a cabinetmaker, doing heavy carpentering and portering for twelve hours a day, he had played football on Saturday afternoons and had usually walked six miles on Sundays. After three months of full military training at the age of nineteen, the patient had first noticed breathlessness and palpitation on exertion, in addition to an occasional cough and frequent giddiness. He was discharged from the Army at that time because of heart disease, but two years later he was again passed as healthy and returned to training, after which the symptoms recurred. From then on, with the history of continual reappearance of symptoms when he attempted heavy physical activity, the course was downward. At the age of thirty-one, he collapsed suddenly and died on his way to the hospital. A second soldier, who had passed his physical examination at the age of forty-six and had campaigned without symptoms in France and Macedonia for three and a half years, after contracting malaria, had developed breathlessness on effort, pain across the chest anteriorly, fatigability, giddiness and frontal headaches, semi-invalided at the age of sixty-three, he was still under treatment at the time of the report. These cases, with 6 others cited, demonstrated typical histories of early well-being, with symptoms of breathlessness and palpitation on exertion, chest pain, giddiness and cough first ushered in at an adult age by some extraordinary incident such as extreme exertion or infection. Frequently, once the symptoms have made their appearance, invalidism develops and death from cardiovascular failure ensues. In Lewis's 9 cases, 2 patients began to have symptoms as early as nineteen years of age, 1 at twenty-seven, 1 at thirty-three, 1 at forty, 1 at forty-one and 2 at forty-eight. The significant chronologic data in these cases are presented in Table 1. Death has occurred early in childhood and as late as ninety-two years of age, as in Reynaud's case, quoted by many writers.

The important symptoms, beginning after years of apparent good health, consist mainly of breathlessness and palpitation on exertion, fatigability, slight cough, sometimes giddiness with hot flushing of the face, headaches and thoracic pain. The period of latency is strongly emphasized by Abbott.¹⁸ The patient in the case reported below was referred by a neuropsychiatrist to whom he had been sent because of nervousness, precordial pain and palpitation were also present in slight degree.

PHYSICAL SIGNS

No disease—certainly no congenital cardiovascular disease—furnishes such unmistakable physical signs as coarctation. Foremost of all find-

ings is the reversed relation of the brachial and popliteal arterial blood pressures. The ordinary increase in pressure from 10 to 50 mm of mercury at the popliteal artery is not present, and the pressure in the brachial artery is usually abnormally high, whereas the popliteal pressure is actually considerably lower.¹⁴ The femoral pulsation is weaker, with a definite lag in its summation, and compared to the radial pulse it is slightly delayed in its travel following ventricular systole. In my opinion, comparison of the pressures in the brachial and popliteal arteries is the *sine qua non* of diagnosis, although

TABLE 1 Important Chronologic Data in Cases of Coarctation Reported by Sir Thomas Lewis¹

CASE No	AGE AT ONSET OF SYMPTOMS	AGE AT DIAGNOSIS	AGE DURING INVALIDISM	REMARKS*
1	19	24	29-31	Sudden death at age of thirty-one
2	49½	50	50-	Patient still alive at age of sixty three
3	19	35	19-	Patient still alive at age of thirty seven
4	40	46	40-52	Death from congestive failure at age of fifty two
5	49	58	50-61	Death from pneumonia at age of sixty-one
6	27	33	40-41	Sudden death at age of forty-one
7	33	42	42-43	Death from congestive failure at age of forty-three
8	41	49	41-49	Sudden death at age of forty nine
9	68	—	—	Patient brought in dead with no history available diagnosis made at autopsy

*Much of the lag in years between the onset of symptoms and the date of diagnosis took place while the patients were under close medical study. Some were cases in Sir Thomas's own clinic. Case 3 had been seen more than once by Sir William Osler and Sir James Mackenzie neither of whom had made the diagnosis.

Lewis¹ stresses inspection of the neck and thorax for enlarged arteries engaged in the collateral circulation. It may be argued that any physician can take blood pressures,* whereas many physicians, particularly in this age of gadgets, are poor observers. Although a brachial arterial hypertension for both systolic and diastolic values is the rule, the brachial pressure is occasionally normal.¹⁴ Bauer and Iverson⁴ encountered difficulty in the diagnosis of their 2 cases of moderate coarctation without signs of collateral circulation. In 1, the arterial pressure in the upper extremity was 30 mm of mercury higher than that in the lower (the key to the diagnosis), and in the other no comparison of the two pressures was made. Both patients were in the throes of cardiovascular decompensation—a condition in which it is unreasonable to expect invariably large, pulsating collateral vessels in the neck and trunk, even if collateral vessels, which do not always form and which at autopsy in these cases were absent, are developed, the reversal of the normal relation of

*The usual blood pressure cuff in use at present is not well designed for recording pressures in the thigh, snug fitting of the cuff being difficult, especially in obese patients. Manufacturers should produce a larger cuff for this purpose.

brachial and popliteal arterial tensions, on the other hand, still pertains

Many other signs that are neither so frequently found nor so nearly pathognomonic include the following: left ventricular enlargement, a systolic murmur precordially and along the routes of enlarged collateral arteries such as the intercostal and the internal mammary arteries, diminished or absent pulsation of the arteries of the lower extremities, capillary pulsations in the face, increased pulsation in the episternal notch, and a tendency to a water-hammer quality of the radial pulses. Perlman¹⁵ states that 9 of 13 patients had a basal dias-

bilaterally, first described by Meckel¹⁶ in 1827 and emphasized by Railsback and Dock¹⁷ in 1929 and by others^{11, 15} (see Figs 2, 5 and 6). This phenomenon, which is found particularly in cases of long standing, is undoubtedly due to rib erosion by the forceful pulsations of the enlarged intercostal arteries. Secondly, one might expect to see variations in the silhouette of the great vessels in the upper mediastinum. Sir Thomas Lewis's description of the x-ray appearance is as follows:

The features of the x-ray silhouette in coarctation that seem to be sufficiently constant to be regarded as significant are two in number. Firstly, there is the increased

FIGURE 5

This roentgenogram shows loss of the expected prominence of the aortic knob. Sulcation of the ribs is barely visible.

tolic murmur, 1 had a precordial systolic murmur and 3 had no cardiac murmur.

X-RAY FINDINGS

A roentgenogram of the thorax usually furnishes strong aids in the diagnosis of coarctation. The first and rather pathognomonic* finding is the scalloping of the inferior borders of the posterior ribs.

*Rarely, other pathologic conditions may cause scalloping of the rib borders. Dr. Edwin M. Wright, of the Department of Roentgenology, University of Michigan, has recently shown me sulcation of the ribs in the x-ray film of a patient suffering from neurofibromatosis. It is conceivable that other types of neoplasm may cause somewhat similar changes.

breadth and density of the shadows of the basal vessels, this is associated with their dilatation but it is not characteristic of coarctation in that it also occurs in cases of simple high tension. Secondly, there is the inability to trace out the aortic arch, a fact particularly significant when it applies to the left oblique position. It is the more noteworthy because a normally developed aorta under the strain of high internal pressure is wide and throws a dense shadow, which can usually be distinguished with ease, even after it passes into the shadow of the vertebral column. In coarctation, the aorta being untraceable, the aorta and its unusually prominent branches rise as a conspicuous column from the heart, high into the thorax and root of the neck. Behind this column at its base there is an area of abnormal clearness opposite the bodies of the 6th, 7th and 8th dorsal vertebrae.

Figures 3 and 4, taken from Lewis, and Figures 6 and 7, which demonstrate the findings in the case presented below, are illustrative. Some eager scientists prefer a more definite delineation of the great vessels by the injection of a contrast medium, such as Diodrast, into the circulation. Careful studies of this type have been reported by Blumenthal and Davis¹⁸ and by Grishman, Steinberg and Sussman,¹⁹

combined, are as pathognomonic as any signs in the science of diagnosis: a decrease of the arterial pressure in the lower extremities, usually to a point below the brachial-artery tension, a small femoral pulsation the summit of whose upstroke lags behind that of the radial pulsation—a lag of 0.145 second according to accurate measurements by Sir Thomas Lewis, visual, palpable or auditory

FIGURE 6

The posteroanterior view of the posterior ribs more clearly illustrates the sulcation of the ribs

and some consider the method the only available test for certain atypical forms of coarctation.²⁰

ELECTROCARDIOGRAPHIC FINDINGS

Except for indications of a left ventricular preponderance in cases with well marked arterial hypertension, the electrocardiograph is of little value in the study of coarctation. Patients showing right-axis deviation have been reported by Stalker,²¹ Moragues et al.,²² Schwartz and Greene²³ and Stewart et al.⁷ Auricular fibrillation might be expected in some patients undergoing myocardial failure,^{8, 20} and right bundle-branch block has been reported.⁸ Negativity and coving of T₁ occurred in 8 of 12 cases studied by Stewart et al.,⁷ and these changes often indicated a poor prognosis.⁹

In summary, it can be said that the following five findings in coarctation of the aorta, when com-

binations of increased pulsations of various arterial branches of the aorta, or a combination of two or more of these, sulcation along the inferior margin of the posterior portions of the ribs, and absence of the aortic knob and abnormal extension toward the neck of the silhouette of the supracardiac vessels

CASE REPORT

A 26-year-old bombardier, a veteran of sixty-five "rough" missions over Germany and France during the 10 months beginning in April, 1944, noticed sharp fleeting pains across the center of the precordium in October, of that year. These pains occurred only during rest, and although palpitation and moderate breathlessness were noticed after physical exertion, there was no associated apprehension. The patient was aware of a steadily increasing incidence of the pains, as well as of a growing nervousness, but he considered both to be due to the fact that he was "crowding in as many missions as possible in order to get it over." On returning to the United States, the patient was found to have a heart murmur with high blood pressure, because of which he was removed from flying status. His current duties in the Army were light, but he continued to have precordial pains (as

many as twenty fleeting attacks a day), slight breathlessness on exertion and indefinite nervousness with irritability. During the preceding few months he had occasionally had brief spells of giddiness. Close questioning revealed no history of cough, hemoptysis, edema, cyanosis, flushing of the face, tingling or coldness of the lower extremities or indigestion. Until the onset of the present illness the patient had always been unusually strong and well.

In the family history it was stated that his father, at the age of 63, had chronic rheumatism, a brother had had inflammatory rheumatism, and another had had a questionable

to the left of the 6th and 7th thoracic vertebrae and along the course of the right 4th and 5th ribs posteriorly. The postmanubrial and precordial dullnesses were normal. A moderate (Grade II or III), fairly high-pitched, late systolic murmur was heard over the precordial 3rd and 4th interspaces and along the left border of the sternum. No diastolic murmur was detected. On exercise the murmurs along the right intercostal spaces became louder, whereas the murmur described in the left scapular region became inaudible when the patient stood erect but returned when he assumed a stooping position — a surprising phenomenon that occurred

FIGURE 7

This roentgenogram shows the clear area in the retrocardiac space in the right oblique view

chorea. Perhaps relevant to the patient's condition was the fact that his mother had suffered from high blood pressure and kidney disease for years before a terminal right hemiplegia at the age of 50.*

Physical examination in April, 1945, disclosed a symmetrically developed man, 72 inches in height and 180 pounds in weight. He appeared to be especially rugged, with no apparent discomfort or pain. When a tension of 160/90 in the left and 158/80 in the right brachial arteries was observed, the right and left popliteal pressures were taken and found to be 98/78 and 98/85 respectively. No pulsations could be seen or felt over the thoracic or abdominal surfaces, but a soft rather high-pitched murmur was distinctly heard just

after some episodes of the exercise (fifty hops on each foot) but not others.† That the patient's arterial bed was elastic is demonstrated by the blood-pressure changes following exercise, the brachial-artery tension varying from 110/90 to 160/80 and the popliteal tension from 98/78 to 105/75. The femoral pulses felt weak, and the dorsalis pedis and posterior tibial arteries were not palpable at any examination.

The urine was normal and serologic tests were negative. The electrocardiogram (Figs 8 and 9) was entirely normal with no evidence of axis deviation. The roentgenograms (Figs

*I am not aware of any studies pertaining to possible familial aspects of coarctation except for a report of cases in a father and son, symptoms beginning in the former at the age of thirty-four and in the latter at the age of fifteen.²⁴

†The systolic murmur at the coarctation is probably formed by the rush of blood from the narrow constricted passage into the larger spindle immediately distal. Perhaps the murmur was not produced in the upright position after exercise because of the increased volume of blood reaching the lower aorta through the collateral arteries, keeping the sides on either side of the stenosis "too full for sound and foam." On stooping over the volume flow may have been impeded enough to allow the production of a murmur.

6 and 7) exhibited absence of the aortic knob in the anterior view and increased height of the great supracardiac vessels in the oblique projections, although the left oblique view was not considered satisfactory.

The patient was given a medical discharge from the Army at the time the diagnosis was first made, 7 months after the onset of symptoms. Five months later he reported that he was having many headaches and an increased fatigability. He found it difficult to do his former work.

COURSE AND PROGNOSIS

Sir Thomas Lewis¹ struck a hopeful note in the prognosis of coarctation, probably because the anomaly can be present long before the appearance of symptoms. It is significant, however, that 6 of the 8 patients he had seen during life were dead

are alive and well whose cases were not reported in the literature, and there are many sufferers with undiagnosed cases, coarctation, however, is a disease of high morbidity and low longevity when once it has become symptomatic. Sooner or later, some episode of infection or unusual physical strain results in successive circulatory evils, and arteritis, aneurysms, bacterial vascular infections, myocarditis and embolization cause cardiovascular reserve to flutter, a fatal outcome subsequently follows.

COMPLICATIONS

The complications, all of which are cardiovascular, have been discussed above. It is interest-

FIGURE 8 *Electrocardiogram — Limb Leads*

at the age of fifty-two, with the exception of 1 who died from pneumonia at the age of sixty-one. Two patients, thirty-seven and sixty-three years of age, were alive at the time of the report. All were symptomatic. Abbott¹³ reported 128 fatal cases before the age of forty in her 200 collected cases, the main causes of death being failure of the myocardium, rupture of the aorta, mycotic endarteritis and aneurysm, frequently with an associated glomerulonephritis, and cerebral hemorrhage, probably based on congenital aneurysm of the cerebral arteries. Many observers have reported rupture of the aorta, in 1 case the rupture occurred 1 cm. distal to the aortic cusps, with emptying into the pericardium,²⁶ and another caused a dissecting aneurysm of the aortic arch.²⁶ Moragues et al.²² cited 5 cases of rupture of the aorta distal to the atresia and reported a case of their own in which the aorta just below the coarctation had ruptured into the esophagus, causing hematemesis. Goodson²⁷ published a case in which the distal aorta ruptured into a bronchus, causing hemoptysis. It is difficult, at present, to be anything but pessimistic in the prognosis of coarctation of the aorta. Of course, many patients

ing to note that only 1 patient is reported to have died from Bright's disease²⁸ — a further indication of an undisturbed blood supply to the kidneys.

TREATMENT

A simple regime of rest, both physical and mental, was the only indicated therapy until recently. If emphasis is placed on the early diagnosis of coarctation, especially before the appearance of symptoms, this form of therapy will doubtless add years to the patient's life. It behooves every examiner to keep the possibility in mind, especially in any case of arterial hypertension. A diligent examination and reappraisal of all cases of high blood pressure may prove most enlightening to the physician. Lewis,¹ investigating the effects of vasodilators on about 30 hypertensive patients in his outpatient department, discovered 5 of the 9 cases he reported. It is not too much to hope that early diagnosis and the early institution of rest, or at least protection against infections and excessive mental and physical rigors, may postpone invalidism and prolong life. Foci of infection should be carefully eliminated.

Those who discover hypertension and other cardiovascular anomalies in children may become particularly helpful in the diagnosis and treatment of coarctation of the aorta. Blumenthal and Davis¹⁵ report the defect in a twelve-year-old child and in a twenty-month-old infant, the latter showing a blood

Greene²³ reported 2 cases in children — a girl of eight and a boy of nine years of age — in whom the atresia also involved the left subclavian artery so that pulsations were absent in the left arm as well as in both lower extremities. Both had an asymmetry of the upper body with a larger face, thorax

FIGURE 9 *Electrocardiogram — Precordial Leads*

pressure of 170 systolic, 110 diastolic, in the upper extremities but no recording being possible in the lower, in the former, a contrast medium of Diodrast was helpful in demonstrating the atresia at the insertion of the ligamentum arteriosum, as well as a dilated internal mammary artery. Schwartz and

and arm on the right. The boy, who had a widely patent ductus arteriosus, exhibited no rib erosion, whereas the girl had erosion of the ribs on the right side only. The authors point out that superficial collateral circulation is rare in children. Eisenberg²⁹ found the diagnosis of aortic coarctation in chil-

dren to be increasing. He added 3 cases in children to the literature. In 1 case the lower extremities were definitely cold to the touch, whereas in another patient, a nine-year-old child, there were a flushed face and intermittent claudication. These authors are cited to emphasize the relative frequency of the defect so that physicians may develop an awareness of it and take steps for treatment before it is too late. The remarkable advances made by the surgeon in the handling of the great blood vessels offer hope. Blalock³⁰ has done much to place this type of surgery on a firm foundation, and Gross and Hufnagel³¹ have already cured coarctation of the aorta anatomically and clinically in a twelve-year-old child. Gross³² reports that they have performed operations in a total of 12 cases, with success in 10. The reports of these authors should be read by all physicians, for no one can help marveling at their courage and expert technic. The surgeon may well have a cure for coarctation.

DIFFERENTIAL DIAGNOSIS

There is nothing typical about the patient's complaints in coarctation of the aorta. Any number of cardiovascular diseases produce the same symptoms. The signs, however, are definite and, when present in combination, are pathognomonic. The findings of a high arterial tension, with a reversal in the relation of the pressures in the brachial and popliteal arteries, and signs of a collateral circulation in the vessels of the thorax and a lag in the summation of the femoral pulse are usually distinctive and should serve to make the physician wary of the diagnosis of other forms of hypertension. The prominence of the aortic knob seen in essential hypertension is usually absent in coarctation. The x-ray film often exhibits a moderate dilatation of the ascending aorta in the uncomplicated case of coarctation, but no aneurysmal enlargement is seen. The silhouette of the dilated supracardiac vessels rises high toward the neck. If complications, such as congestive failure, aneurysms, bacterial vascular infections and embolic phenomena, occur, the picture may be confused. But the changes in the relative arterial tension, the lag of the femoral pulse summit and the x-ray findings—in the great vessels, scalloping of the ribs—should be elucidative in such cases.

* * *

Since the first case report of coarctation of the aorta by Paris³³ in 1791, the anomaly has attracted the attention of many great physicians—for example, Sir Ashley Cooper (1818), Meckel (1824), Laennec (1826), Reynaud (1828), Rokitsansky (1848), Barie (1886), MacCallum (1900), Minkowski (1901), Libman (1902), Pappenheimer (1905), Mönckeberg (1907), Abbott (1928) and Sir Thomas Lewis (1933). The defect is embryologic and occurs at all ages. The symptoms, which usually do not appear before adult life, are similar to those in many

types of cardiovascular failure and are not distinctive. When they once appear, the outlook is usually not bright and various degrees of invalidism are the rule. The span of life is shortened, cardiovascular complications of various types being the almost universal cause of death. The signs are definite and, when exhibited in combinations of two or three positive findings, pathognomonic. One can be sure that the defect is not rare. It has been said that coarctation occurs in about 0.10 per cent of the entire population.³⁴ In a routine examination of men between the ages of eighteen and thirty-five for military services, the known incidence was approximately 1 in 10,000.¹⁵ In a large army general hospital, 113 of 2685 patients studied on the medical service had hypertension, and 39.7 per cent of these were under thirty years of age.³⁵ A search through such fields as this, including the Veterans Administration Medical Service, is bound to uncover more cases of coarctation. Since, more than ever before, cure of this disease can be hoped for, every diagnostician should make a search for it. The diagnosis is easy and interesting. Perhaps it is not too much to hope that the surgeons will be able to cure many of the patients with this disease in the not too distant future.

HORMONE-PRODUCING TUMOR OF ADRENAL CORTEX, WITH CONGENITAL ABSENCE OF CONTRALATERAL ADRENAL GLAND

Report of a Case

HARRY M SPENCE, M D,* AND F GREGG THOMPSON, JR, M D †

DALLAS, TEXAS, AND ST JOSEPH, MISSOURI

ALTHOUGH hyperfunctioning tumors of the adrenal cortex are rare, they are the subject of an increasing number of reports in the current literature owing both to improved diagnostic procedures, such as perirenal air insufflation and assay of the sex hormones excreted in the urine, and to increasing knowledge of the physiology of the adrenal cortex, especially in its interlocking relation with the function of the pituitary gland and the gonads.

The purpose of this communication is to present a case of a hormone-producing tumor of the adrenal cortex characterized by the symptomatology of Cushing's syndrome and associated with complete absence of the opposite adrenal gland. In addition the recent literature on such tumors is briefly reviewed. Grollman¹ presented an exhaustive review of the literature of adrenal physiology and pathology up to 1936.

CLASSIFICATION OF ADRENAL TUMORS

In classifying adrenal tumors it must be borne in mind that the human adrenal gland is actually two glands fused together in development in one enveloping capsule. The medullary portion is derived from the neural crest of the ectodermal germ layer, and tumors of the medulla are therefore classified according to the sympathetic-nervous-system cell type from which they originate into the following groups: sympathoblastoma (from the basic nerve cells), ganglioneuroma (from the cells of the sympathetic ganglion), and pheocytoma or paraganglioma (from the pheocytes). The first two types occur primarily in children, and the last occurs chiefly in adults and is characterized by hypertensive crises.

Tumors derived from the adrenal cortex, on the other hand, are mesodermal, glandular tumors that may be cytologically divided into hyperplasias,

adenomas and carcinomas. Cahill,²⁻⁵ who has written extensively on the subject, offers the following clinical classification: those with no recognizable hormonal changes, those with changes due to excess androgens that cause adult masculinity in the female child, masculinity in the female adult and adult masculinity in the male child, those with changes due to excess estrogens causing femininity in the adult male, those with changes due to excess androgens and other steroids and exemplified by Cushing's syndrome with associated sexual changes in the male and the female, and those with changes due to excess of other steroids related to metabolism which produce Cushing's syndrome without sexual changes in the male and the female.

The changes in the female child with a masculinizing tumor of the adrenal cortex have been described as pseudohermaphroditism. The first successful operation for a hormone-secreting adrenal tumor in a child was performed in a case of this type in an eighteen-month-old girl with virilizing symptoms reported by Collett⁶ in 1924. Several additional successful cases have been reported, as well as a number of deaths. It has been noted in the latter group that associated metabolic changes were usually present and that acute adrenal insufficiency was a factor in the fatal outcome.

The term "adrenocorticotrogenital syndrome" or "adrenal virilism" has been applied to the occurrence of masculinizing symptoms in adult women. This condition is characterized by hirsutism, amenorrhea, atrophy of the breasts, enlargement of the clitoris and male habitus. Cahill emphasizes that of several hundred cases of virilism investigated at his clinic, only a comparatively small proportion were found to have actual tumors of the adrenal cortex.

Masculinizing tumors in immature males are rare. They result in precocious puberty, with its associated bodily changes. The so-called "infant Hercules"

*Associate professor of clinical urology, Southwestern Medical College, urologist Parkland and Baylor hospitals and Dallas Medical and Surgical Clinic.

†Consulting surgeon, Ellis Fischel State Cancer Hospital, Columbia, Missouri; attending surgeon, Missouri Methodist and St. Joseph hospitals, St. Joseph, Missouri.

type belongs in this category, although such cases have also been reported without adrenal tumors

Feminizing tumors in the adult male are also quite rare. Simpson and Joll⁷ reported the sixth such case in 1938. In their case excessive estrogenic substance, which had been excreted in the urine preoperatively, disappeared after successful operation and reappeared when metastatic recurrence became evident.

The group of cases with symptoms due to excess androgens and other steroids is exemplified by cases of Cushing's syndrome with associated sexual changes. This combination occurs principally in adult females, although an increasing number are being reported in children, and accounts for the largest number of tumors of the adrenal cortex, although it is not confined to tumor cases.

Cushing's syndrome without sexual changes, which is due to excess production of sterols related to metabolism alone, is discussed below.

It is thus seen that the clinical picture produced by a tumor of the adrenal cortex depends on the sex and age of the patient at onset and on the varying combinations of androgenic, estrogenic and metabolic hormones secreted. Cahill¹²⁻⁵ points out that the excess production of the metabolic hormones causes the functional or actual atrophy of the opposite gland. On the contrary, excess production of the androgenic hormones alone does not cause depression of the production of the life-maintaining substances by the opposite gland. This is of great importance in the prognosis following surgical extirpation of tumors of the adrenal cortex.

RELATION OF CUSHING'S SYNDROME TO ADRENOCORTICAL TUMORS

In 1932 Cushing⁸ described a syndrome, which has since borne his name, characterized by rapidly developing obesity confined to the face, neck and trunk (so-called "buffalo obesity"), plethora of the face, purplish striae over the lower abdomen and thighs, acne, amenorrhea and hirsutism in the female and impairment of sexual powers in the male. In addition, hypertension, frank or latent diabetes, disturbance of the nitrogenous metabolism and osteoporosis are frequently present. Furthermore, although not necessarily a part of the syndrome, virilism in women, as evidenced by masculine voice, atrophy of the breasts and hypertrophy of the clitoris, is often present. Cushing's syndrome occurs oftenest in adult women, next in frequency in children and less often in men.

Cushing attributed the syndrome to excessive secretion from a basophilic adenoma or hyperplasia of the basophilic cells of the anterior portion of the pituitary gland. Subsequently, as numerous cases of the syndrome appeared in the literature, it became apparent that the symptoms of many, if not a majority, were due not to primary pituitary disease but to hormone-secreting tumors of the adrenal

cortex, whereas in a few cases thymic tumors or arrhenoblastomas of the ovary were found to be the principal pathologic lesions. In a considerable number of autopsied cases of Cushing's syndrome no pituitary basophilism was found, and in other series of routine post-mortem examinations basophilic adenomas were found, frequently with no clinical findings referable to them.⁹⁻¹³

It may be concluded, then, that the prevailing opinion at present is that the likeliest finding in a patient exhibiting Cushing's syndrome is a tumor of the adrenal cortex. This is particularly true in cases in which sexual changes accompany the syndrome proper.

The importance to the surgeon of the relation between Cushing's syndrome and tumors of the adrenal cortex, apart from the necessity of investigating the adrenal glands in all cases of the syndrome, lies in the fact that the prognosis for recovery after operative removal of such a tumor associated with Cushing's syndrome is much poorer than when symptoms of virilism alone are present. Thus, Thompson and Eisenhardt¹² found that in 22 surgical cases of adrenal tumor with Cushing's syndrome, 18 patients died of shock resembling adrenal insufficiency in the immediate postoperative period, whereas in cases of true virilism operative recovery is the rule. Cahill¹²⁻⁵ also notes that shock from adrenal insufficiency does not occur after the removal of nonhormonal tumors of the gland or in the cases marked by sex-hormone changes only. Although recognizing that patients with Cushing's syndrome have recovered after surgical removal of an adrenal tumor, Cahill points out that unrecognized metastases are often present, and he suggests that this fact may influence the immediate recovery. Undoubtedly, the explanation of the uniform picture of postoperative acute adrenal insufficiency lies in the functional or actual atrophy of the gland on the opposite side.

DIAGNOSIS

The diagnosis of a hormone-producing tumor of the adrenal cortex is made on the clinical examination of the patient, pertinent laboratory data and roentgenographic findings. Often, however, the diagnosis can be confirmed only by surgical exploration or autopsy.

Clinical Data

As emphasized by Cahill, the appearance of sexual precocity before puberty, pseudohermaphroditism in girls, heterosexual changes in adults and the development of Cushing's syndrome in either male or female, child or adult, are indicative of pathologic adrenal physiology, and determined effort must be made to prove or exclude the existence of the tumor in such cases.

When the tumor is suspected, the most important physical finding is a palpable mass in the region of the adrenal glands.

Laboratory Data

The laboratory tests indicated in addition to the routine blood counts and urinalysis are the blood chemical determinations of the nonprotein nitrogen, cholesterol and chloride, the glucose-tolerance curve and the assay of the excess urinary excretion of the male and female sex hormones. The latter tests are becoming increasingly important.

Lukens¹⁴ states that thirty separate chemical substances with the sterol nucleus having hormonal effects have been isolated from the adrenal cortex. These include regulators of water and salt distribution and excretion, carbohydrate, fat and protein metabolism, growth factors and sex development. The masculinizing sex hormones have been identified as 17-ketosteroids. These may be estimated colorimetrically. The feminizing hormones are similar to the estrogens.⁴

By biologic assay, Frank¹⁵ found that 7 out of 8 patients with adrenal carcinoma had elevated urinary estrogen excretion with a negative pregnancy test, and he concluded that the elevated estrogen finding was of value in differentiating a malignant growth from an adenoma. Wilhelm and Gross¹⁶ reported a case of Cushing's syndrome due to a large adrenal adenoma in which the urinary androgens were markedly elevated, with a normal estrogen level. Reilly¹⁷ has also reported a case in a six-and-a-half-year-old boy with sexual precocity due to an adrenal adenoma in whom the androgen excretion was that of an adult male, whereas the estrogen excretion was not elevated. In 2 cases of carcinoma of the adrenal gland in women — one of whom exhibited virilism and the other a Cushing's syndrome — Oppenheimer and Silver¹⁸ found the urinary estrogens markedly elevated. The feminizing tumor in an adult male case of Simpson and Joll,⁷ which showed an increase of estrogen excretion, was mentioned above. Marked elevation of both androgen and estrogen urinary excretion has been reported by Gross¹⁹ in the case of a three-and-a-half-year-old girl who showed a masculine habitus, and enlarged clitoris and pubic hair due to an adrenal carcinoma. On the other hand, cases with hormonal changes have been described in which the excretion of the urinary sex hormone has been normal, as in the case reported by Cahill of a Cushing's syndrome due to an adrenal tumor with no sex changes except amenorrhea.

Since the clinical differentiation between tumor of the adrenal cortex and cortical hyperplasia is difficult, owing to the fact that both lesions may present the same symptom complex, Talbot, Butler and Berman²⁰ have developed a method to distinguish between the two by fractional analysis of the 17-ketosteroids.

In summary, it may be stated that the demonstration of an elevated urinary excretion of androgenic and estrogenic substances is of value in the

diagnosis of an adrenal tumor if positive but that a tumor may be present with a negative test. More research and wider usage of these tests are necessary to establish their final clinical value.

X-ray Data

An adrenal tumor often shows up as a soft-tissue shadow in the plain roentgenogram. Another frequent and valuable finding is downward displacement of the kidney in the pyelogram.

The x-ray diagnosis of adrenal tumors has been amplified by visualization of the adrenal glands by perirenal insufflation of air or oxygen. This procedure has been popularized in this country by Cahill,²⁻⁵ who has done several hundred injections without significant untoward reaction. In essence, the procedure consists in the injection of air into the perirenal tissues with subsequent exposure of films at intervals of from six to thirty-six hours to bring out the adrenal contour by contrast. Fish²¹ reported 2 fatal cases from air embolism in approximately two hundred injections, and he recommends oxygen as preferable to air. Cope and Schatzki²² advocate a modified technic in which 200 cc of air is injected into the triangular fat pad below the kidney and report no complications in one hundred and sixty-three injections. Roome²³ advocates perirenal insufflation as preferable to surgical exploration when a tumor is suspected. Hyman and Wilhelm²⁴ on the other hand, believe that the information gained from perirenal insufflation is of limited value and that the method should be used only as a last resort on account of its dangers.

The use of pneumoperitoneum in the following case was of definite value, although not diagnostic.

CASE REPORT

G. E. B. (60316), a 24-year-old married woman, was admitted to the Dependents' Ward, United States Naval Hospital, Corpus Christi, Texas, on March 29, 1945, complaining of a tumor in the abdomen of 2 months' duration. The patient stated that she had always been well until she injured her back in 1942, while riding a roller coaster. Following this injury she was in a body cast for 10 weeks. After the accident, she failed to regain strength and had frequent episodes of nausea and vomiting. One year before admission an increased growth of hair on the face had prompted her to shave her face on several occasions. She had also noted an excessive growth of hair on the arms and legs. There had been a complete amenorrhea for 2 years prior to admission. This had been attributed to hypothyroidism, for which she had received thyroid therapy without improvement. She had been married 1 year before admission, and the libido was stated to be normal. No pregnancy occurred despite the fact that contraceptives were not used. Excessive dryness of the skin, puffiness of the face and increased fat deposits about the shoulder girdle, with no change in the body weight, had been noted for several months.

Six months before admission, the patient had a sudden hemoptysis, which was found to be tuberculous in origin. She was treated with bed rest and artificial pneumothorax at a state tuberculosis sanatorium. While under treatment for pulmonary tuberculosis, she developed pain in the left upper quadrant of the abdomen and a palpable mass led to admission to this hospital. There were no symptoms referable to the urinary tract.

The past and family histories were irrelevant except as stated above.

Physical examination revealed a fairly well developed and well nourished woman with a general appearance suggestive of Cushing's syndrome. The height was 63 inches, and the weight was 106 pounds. The skin was abnormally dry, with mild acne on the face. There was a "buffalo type" of obesity involving the neck and shoulder girdle. The face was puffy, and there was an excessive amount of male type of hair on the cheeks, upper lip and chin. There was no adenopathy of the neck, and the thyroid gland was normal to palpation. The breasts were somewhat atrophic. The thorax was normal in contour. Examination of the chest showed the left lung to be clear, with physical signs of pneumothorax on the right. The heart was normal. The blood pressure varied between 140/120 and 128/116. There were striae over the lower abdomen. The pubic hair line was of masculine distribution,

sulfonephthalein test showed normal renal function in both kidneys.

X-ray examination of the chest revealed the heart and great vessels within normal limits. The left lung field was clear. There was a partial pneumothorax on the right side. In the apex of the collapsed lungs there was an area of increased density interpreted as an old tuberculous lesion. A plain film showed a large oval shadow measuring 14 by 11 cm. lying just to the left of the 12th dorsal and 1st, 2nd and 3rd lumbar vertebrae, overlapping the lower two thirds of the kidney shadow. There was a 2-cm linear calcified shadow along its outer margin. Retrograde pyelograms revealed a normal kidney and ureter on the right. On the left, in addition to the mass, there was a slight hydronephrosis and hydroureter, apparently unrelated to the mass (Fig 1).

FIGURE 1 Retrograde Pyelogram Showing Mass on the Left Side

extending toward the umbilicus. There was a palpable, tender, round tumor in the left upper quadrant, extending into the left flank. It was movable and descended with inspiration. There was no fixation to the abdominal wall. The tumor measured approximately 10 by 15 cm.

The external genitalia were normal, with no hypertrophy of the clitoris. Pelvic examination revealed an infantile uterus with no masses in the adnexal regions. The extremities appeared slender in proportion to the trunk. There was an excessive growth of fine hair on the arms and legs.

Examination of the blood disclosed a red-cell count of 5,100,000, with a hemoglobin of 15 gm, and a white-cell count of 10,000, with a normal differential. The fasting blood sugar was 80 mg, the blood cholesterol 140 mg, and the nonprotein nitrogen 28 mg per 100 cc. The blood Kahn reaction was negative. The urine was normal. The sedimentation rate was 21 mm in 1 hour.

Cystoscopic examination showed a normal bladder, with no obstruction to passage of ureteral catheters on either side, specimens obtained from each kidney were normal on microscopic examination and were sterile on culture. A phenol-

There was no evidence of distortion or displacement of the kidney by the tumor. Stereoscopic views localized the tumor anterior to the kidney and posterior to the transverse colon. A pneumoperitoneum was performed, and films in several planes confirmed the location of the tumor as shown in previous films.

The preoperative diagnosis was Cushing's syndrome due to adrenal tumor. The pulmonary tuberculosis was considered to be coincidental and, since the process was controlled, not to contraindicate surgery.

On April 13 the patient was operated on under spinal anesthesia. A transverse incision was made from the outer border of the left rectus muscle extending laterally approximately 15 cm. The incision was deepened to the perirenal space, and the kidney was explored and found to be normal. Further exploration of the wound anteriorly and extraperitoneally revealed a soft, encapsulated, ovoid tumor, the size of a grapefruit, with a vascular pedicle on its upper medial aspect.

The tumor was mobilized from a few light surrounding adhesions, and the pedicle was clamped, cut and ligated. A

search for the left adrenal gland failed to disclose any semblance of adrenal tissue. The wound was closed in layers with a cigarette drain.

The pathological report, by Dr H B Willford was as follows:

Grossly the specimen consists of a large, oval encapsulated, soft tumor measuring 13 by 9 cm. On section the tumor tissue is golden yellow, edematous and supported by a fibrous reticulum (Fig 2).

On microscopic examination the tumor cells are arranged in small groups separated by fine connective-tissue strands (Fig 3). No lumens are present. The cell nuclei are hyperchromatic to pale and vary in size. Most of the

of plasma, glucose and saline and intramuscular injections of desoxycorticosterone. The patient showed a transitory response and regained consciousness temporarily after each injection of the hormone. Despite the supportive treatment, however, she gradually became weaker and expired 48 hours after operation.

Autopsy At post-mortem examination, which excluded the head and was done 2 hours after death, the external appearance was the same as that on physical examination. There were nodules of active tuberculosis in the apex of both lungs, the right lung was partially collapsed. The operative incision was clean, as was the site from which the tumor had been removed. All ligatures were intact, and there was no evidence of hemorrhage. No sign of adrenal tissue remained

FIGURE 2 Photograph of the Tumor after Removal

tumor cells show a cytoplasm of granular, foamy texture and stain a faint pink. Vascularity is generally good but becomes sparse centrally. There is no true degeneration. Along many of the blood-vessel spaces, large granular and fatty-appearing cells are present. A few giant cells are noted, with large granular nuclei or multiple nuclei. This is considered to be an adrenal tumor of the zona glomerulosa type.

Diagnosis Malignant adenoma of the adrenal cortex.

The postoperative course for the first 24 hours was uneventful. There was no evidence of shock. The temperature was 99.8°F, the pulse 105, and the respirations 20. The blood pressure was 132/98. At the end of 36 hours, however, the patient's condition began to change for the worse. The pulse rose to 160, and the temperature began to climb rapidly, reaching 106°F before death. The respirations rose to 30 and became shallow. The patient's color was ashen. The blood pressure became imperceptible, and she relapsed into a semicomatose state. Supportive treatment, which was started immediately after the patient began to show signs of collapse, included 100 per cent oxygen in a tent, transfusions

on the left. The uterus and ovaries were infantile in character, with no corpora lutea. The most striking finding was the complete absence of the right adrenal gland. Prolonged systematic search of the retroperitoneal tissues and the abdominal contents showed no vestige of adrenal tissue, and no adrenal blood supply could be identified. There was no evidence of tuberculous involvement of these tissues. It was the opinion of the pathologist, as well as of all present at the autopsy, that this case represented a congenital aplasia of the right adrenal gland and that at the time of death there was no adrenal tissue in the body.

The wisdom of demonstrating an adequate adrenal gland on the side opposite the tumor is apparent from this case. It was so obvious, however, that the patient's well-being and life were jeopardized by the tumor that its immediate removal seemed justified, and the ultimate outcome would have been the same had surgery been withheld.

STATE OF THE ADRENAL GLAND OPPOSITE TO THAT CONTAINING TUMOR

Although it had previously been noted that in tumor of the adrenal cortex the contralateral gland exhibited varying degrees of atrophy, Cecil,²⁵ in 1933, was the first to emphasize this fact when he reviewed the literature and found that in 30 per cent of cases the adrenal gland on the side opposite the tumor was either absent or atrophic to an extent insufficient to support life. Cecil considered the process in cases of reported absence of the gland to be one of advanced atrophy rather than true aplasia.

In 1941 Weinberg,²⁶ in a review of 34 cases of neoplasm of the adrenal cortex occurring in the preceding fourteen years in which the clinical ob-

amples of this process in other endocrine glands are found in the involution of the insulin-forming beta cells of the pancreas that accompanies tumors of the islands of Langerhans, and the atrophy of the normal parathyroid glands that takes place in the presence of a parathyroid tumor. Furthermore, excess administration of estrogenic substances has been noted to cause involution of the ovaries, and similar changes in the testicles have been induced by excess androgenic hormone injection. Selve²⁷ has proposed the term "compensatory atrophy" for this phenomenon.

From the experimental point of view, Ingle and Kendall²⁸ started with the observation that transplants of the adrenal glands do not regenerate in the presence of one intact gland and demonstrated that the administration of large amounts of corti-

FIGURE 3 Photomicrograph of a Section of the Tumor

servations on the state of both adrenal glands had been confirmed at autopsy, found that atrophy was encountered in 21 cases, or 62 per cent, and that the gland was completely absent in 2 cases. In 10 cases the gland was reported as "grossly normal." He also described a case in which bilateral adrenal atrophy had been caused by a tumor of an accessory adrenal gland.

The cause of this glandular atrophy on the supposedly normal side is excess production of the metabolic hormones by the tumor, with consequent suppression of function of the normal tissue. From the teleologic standpoint, the tumor relieves the normal gland of the necessity of functioning. Ex-

to normal rats produced atrophy of the adrenal cortex. They found this effect to be mediated through the adrenotropic principle of the anterior portion of the pituitary gland.

In 1926 Feinblatt²⁹ reported the case of a thirty-two-year-old woman with virilism dying of exhaustion, who at autopsy showed a carcinoma of the right adrenal gland and a complete absence of the one on the left. In 1927 Gordon and Browder³⁰ described a case of a left suprarenal carcinoma causing puberty praecox in a three-year-old boy who died of pulmonary metastases, and at autopsy no suprarenal gland was found on the right. Lukens et al,³¹ in 1937, reported the case of a twenty-nine-

year-old woman with Cushing's syndrome who was operated on with removal of an encapsulated tumor from the right adrenal gland and died on the eighth postoperative day of shock. Autopsy revealed complete absence of the left adrenal gland and the residual adrenal tissue on the right side to be about half the normal size. Lukens stated that the autopsy files of the University of Pennsylvania Hospital from 1894 to the date of his report contained records of 3 additional cases of absence of the gland, none, however, had been associated with contralateral tumor. Absence of the left adrenal gland was found on surgical exploration by Goldheizer²² in the case of an eighteen-year-old girl with hirsutism, the right adrenal gland in this case was enlarged but no extirpation of tissue was done in view of the missing left gland.

Cahill,² using perirenal insufflation in investigating several hundred cases of suspected adrenal disease, found that in 9 per cent only one adrenal gland could be demonstrated by this method.

TREATMENT

The treatment of these tumors is primarily by surgical removal. The operation is doomed to failure, however, unless a carefully planned program to counteract postoperative acute adrenal insufficiency due to reduced function of the opposite gland is carried out. According to Cahill the most important factor in the surgical management of these cases is the anticipation, prevention or control of such failure.

At the time of the operation it is essential to determine both the presence of the supposedly normal gland and its capacity to support life. In some cases in which the opposite gland was described as half the normal size, the patients have recovered.²³

From the technical standpoint, two surgical approaches are frequently used — namely, the lumbar extraperitoneal route and the abdominal transperitoneal route. Transthoracic access to the adrenal glands has been described but has found little popularity in the literature. Walters²⁴ recommends exposure of both glands and uses the usual loin-kidney incision. Young²⁴ explores both glands simultaneously through the lumbar regions, using a specially devised spreader type of retractor. Cahill² recommends the anterior, abdominal, transperitoneal approach through an oblique subcostal incision as giving the best exposure and permitting exploration of the opposite gland through the same incision.

All who have had experience with the surgical removal of tumors of the adrenal cortex emphasize that immediate aggressive postoperative steps must be taken to combat acute adrenal insufficiency. The majority of deaths occur in from twenty-four to forty-eight hours after operation of collapse, which does not respond to the usual antishock therapy of fluids, blood transfusion and stimulants. If ade-

quate amounts of adrenocortical extract are given, however, it may be expected that the remaining adrenal tissue will regain its capacity to produce a sufficient amount of the hormones essential to life. Walters, who has successfully operated on 10 patients, attributes his success to the availability of potent adrenocortical preparations to tide the patient over the critical period immediately after operation.

In a case of Cushing's syndrome due to an adenoma in which the patient was successfully operated on, Wilhelm and Gross¹⁶ used the blood-pressure readings as a guide for the dosage of adrenocortical extract. They point out that there is a danger of overdosage as shown by the development of oliguria and anasarca from the seventh to the twelfth postoperative day. Grollman²⁵ suggested a dosage of 200 rat units of adrenocortical extract a day as appropriate for the immediate postoperative period.

PROGNOSIS

It should be recalled that postoperative fatalities are much more frequent in the cases with metabolic changes than in those in which sexual changes predominate.

In 1933 Cecil²³ stated that in 39 per cent of the operated cases the patients died of shock caused by adrenal deficiency. In 1941 Weinberg²⁶ wrote that the outcome is usually fatal shortly after surgery. In 1943 Thompson and Eisenhardt¹² found that in 22 cases of adrenal tumor with Cushing's syndrome, 18 patients who were operated on with removal of the tumor died in the immediate postoperative period of shock resembling adrenal insufficiency. In a few cases death occurred in spite of "fairly adequate" measures to combat the deficiency.

SUMMARY

The subject of hormone-producing tumors of the adrenal glands is reviewed, with reference to classification, relation to Cushing's syndrome, diagnosis, treatment and prognosis.

A case of Cushing's syndrome due to an adrenal tumor is reported in which the patient died of acute adrenal insufficiency thirty-six hours after operative removal of the tumor and in which, at autopsy, complete absence of the opposite adrenal gland was found. This is the fourth such case in the literature.

From a review of the available literature it is concluded that an increasing number of successful operative removals are being done owing to better postoperative therapy. The prognosis, however, is still exceedingly grave in the cases associated with Cushing's syndrome, because of the atrophy and insufficiency of the supposedly normal gland.

ACUTE APPENDICITIS OCCURRING DURING THE COURSE OF OTHER DISEASES*

ELLIOTT S HURWITT, M D †

NEW YORK CITY

THE diagnosis of acute appendicitis is usually considered whenever a patient develops symptoms or signs suggesting an acute intra-abdominal inflammatory lesion. There are many contributions dealing with the differential diagnosis of abdominal symptomatology, in which many diseases that mimic appendicitis are enumerated and classified. The inference usually drawn is that laparotomy on the basis of an erroneous diagnosis of acute appendicitis is warranted if some morbid process is encountered to account for the clinical picture, such as a twisted ovarian cyst, inflamed Meckel's diverticulum, regional ileitis, neoplasm, volvulus or intussusception. Emphasis is usually placed, however, on the dangers of operating on a patient whose abdominal complaints are based on some other underlying systemic or regional disorder. Prominent among the more frequent of these diseases are pneumonia, tonsillitis, upper respiratory infections, pyelitis, cardiac failure, mesenteric thrombosis, diabetic ketosis and syphilis of the central nervous system. It is beyond the scope of this communication to undertake a discussion of these diseases and the features in the differential diagnosis that distinguish them from appendicitis. The problems of diagnosis and operative indications are particularly compli-

cated in patients already hospitalized, or under treatment for some nonrelated disorder, who, under observation, develop acute abdominal complaints referable to the lower abdomen. Although under ordinary circumstances such symptoms are sufficiently specific to warrant a diagnosis of appendicitis, under these special conditions there is a tendency to dismiss the possibility of an independent lesion, and to attempt to correlate the new symptomatology with the pre-existent disorder. The delay in therapy thus engendered may be prejudicial to the interests of the patient, whose best chance for recovery may depend on removal of the acutely inflamed appendix.

It is the purpose of this paper to emphasize the necessity for laparotomy in the presence of persisting symptoms and signs ordinarily associated with acute appendicitis, despite the pre-existence or coexistence of other diseases that include abdominal complaints among their possible manifestations. The following cases are illustrative.

CASE 1 J T (MSH 503817), an 8-year-old girl, previously in good health, was admitted to the hospital on April 6, 1943, suffering from an acute respiratory infection of 24 and abdominal pain of 6 hours' duration. On the previous day, she had begun to cough, and a sore throat and coryza had been noted. Six hours before admission she had begun to experience abdominal pain localized to the region of the umbilicus and had vomited three times. On examination, the temperature was 98.8°F, the pulse 78, and the respirations 24. A purulent pharyngitis was present.

*From the Surgical Service of Dr Harold Neuhof, Mt. Sinai Hospital, New York City.

†Sarah Welt Fellow in Pediatric Surgery and Pathology, Mt. Sinai Hospital; formerly resident surgeon Mt. Sinai Hospital.

together with greatly enlarged, reddened tonsils. There was a generalized lymphadenopathy, and the spleen was palpated one fingerbreadth below the left costal margin. The abdomen was soft, with persistent tenderness in the right lower quadrant. Rectal examination disclosed no tenderness. Examination of the blood revealed a white-cell count of 18,100, with 73 per cent neutrophils and 22 per cent lymphocytes. An appendectomy performed shortly after admission disclosed an acute phlegmonous appendicitis. The convalescence was uneventful. A throat culture revealed beta-hemolytic streptococcus and alpha-hemolytic streptococci. Blood for heterophil agglutination was positive in a dilution of 1:16.

CASE 2 A C (M S H 486225), a 14-year-old boy, was admitted to the hospital on February 27, 1942, with a history of abdominal pain, which had shifted to the right lower quadrant, and vomiting of 2 days' duration. The onset of pain was associated with a sore throat and a temperature of 101°F. On examination, the temperature was 101°F, the pulse 80 and the respirations 20. The patient appeared acutely ill, and complained of severe pain in the lower abdomen. There was a marked postnasal discharge, and white follicles were present on the right tonsil. The peripheral lymph nodes were slightly enlarged. Lower abdominal tenderness was present chiefly in the right lower quadrant, with some rigidity to the right of the umbilicus. Rectal examination revealed tenderness on the right side. Urinalysis showed a slight trace of albumin. Shortly after admission, an appendectomy was performed, the appendix revealing acute inflammation. The nasopharyngitis subsided, and the patient was discharged on the 8th postoperative day.

CASE 3 O G (M S H 454412), a 32-year-old painter, was admitted to the hospital on March 29, 1940, with complaints of a severe sore throat, general malaise and fever of 3 days' duration. During 12 hours prior to admission he had experienced pain in the right lower quadrant with radiation to the epigastrium, followed by vomiting. The pain in the lower abdomen became progressively severer. On examination, the temperature was 100°F, the pulse 92, and the respirations 26. The patient appeared acutely ill. Marked follicular tonsillitis was present. There were both tenderness and spasm in the right lower quadrant. Appendectomy was performed promptly, and an acute gangrenous appendicitis was encountered. Postoperatively the temperature rose to 104°F, associated with an increase in the follicular tonsillitis. Sulfanilamide was given, and the temperature subsided to normal on the 4th day, with corresponding clinical improvement. The wound healed by primary union, and the patient was discharged on the 8th postoperative day.

CASE 4 H B (M S H 488688), a stocky 50-year-old man, was admitted to the hospital on April 21, 1942, complaining of lower abdominal pain of 48 hours' duration. The diagnosis of diabetes mellitus had been established 15 years previously, and the disease had been controlled during this period by dietary regulation without insulin. On examination, the temperature was 100.2°F, the pulse 90, and the respirations 26. Moderately advanced neuroretinopathy was present. There was localized tenderness, without spasticity, in the right lateral portion of the abdomen near the level of the umbilicus, no tenderness could be elicited on rectal examination. Urinalysis revealed a +++ test for sugar but no acetone. During a 24-hour period, the diabetes was brought under control with insulin, there was no increase in symptomatology, and no further temperature elevation. Lower abdominal pain and tenderness persisted, and operation disclosed the appendix as the seat of an acute phlegmonous inflammation. The postoperative course was uneventful, the wound healing by primary union, and the patient was discharged on the 12th day, when he was receiving 20 units of protamine insulin daily and was sugar free on a daily diet of 150 gm of carbohydrate, 80 gm of protein and 80 gm of fat.

CASE 5 L S (M S H 497398), a moderately obese, 45-year-old man, entered the hospital in November, 1942, with an acute myocardial infarction, pericarditis and cardiac decompensation. A subtotal gastrectomy for duodenal ulcer had been performed in July, 1938, after 9 years of unsuccessful medical treatment. On admission, the temperature was 102°F, the pulse 100, and the respirations 30. A pericardial friction rub was present, and the heart sounds were of only fair quality, coarse rales were heard at both lung bases. The

electrocardiographic changes were those of an acute infarction of the posterior wall. On the 3rd hospital day the patient developed a left hemiparesis, which was attributed to a cerebral embolus from a detached mural thrombus. The temperature gradually subsided, the sedimentation time rose to normal, the friction rub became intermittent, and the signs of both the hemiparesis and the congestive failure began to clear. Thirty-seven days after admission, lower abdominal cramps, followed by nausea and vomiting, developed. There was tenderness without spasm in the right lower quadrant and some tenderness to the right on rectal examination. The temperature remained normal. Examination of the blood showed a white-cell count of 15,300, with 78 per cent neutrophils — 2 weeks previously the white-cell count had been 11,200, with 66 per cent neutrophils. Examination of the stool for occult blood was negative.

Because of the bizarre clinical course, with recurrent pericarditis, pneumonia, hemiparesis and microscopic hematuria, the possibility of a vascular basis for the abdominal symptomatology was considered. Among the diagnoses entertained were mesenteric thrombosis and periarteritis nodosa. The patient was observed for about 8 hours, during which the symptoms and signs persisted without much change. After a surgical consultation laparotomy was performed disclosing acute phlegmonous appendicitis. The postoperative course was uneventful.

CASE 6 F P (M S H 503543), a 32-year-old man, was admitted to the hospital on March 26, 1943. He had been awakened 8 hours previously by pain in the right lower quadrant that was nonradiating and was associated with nausea, without vomiting. Three years previously he had contracted syphilis and gonorrhea, both of which had been treated intensively, antisyphilitic therapy was still being administered. On examination, the temperature was 100°F, the pulse 108, and the respirations 32. There was tenderness in the right lower quadrant, with slight spasm. Rectal examination disclosed tenderness to the right. Despite the clear-cut evidence of acute appendicitis, there was a tendency on the part of some observers to interpret the clinical picture in terms of syphilitic changes. Appendectomy was promptly performed, however, and disclosed an acute phlegmonous appendicitis.

CASE 7 R L (M S H 452212), a 13-year-old girl, with an indefinite 4-year history of "kidney trouble," was admitted to the hospital on February 7, 1940. On the morning of admission she complained of abdominal distress, followed by severe epigastric cramps, vomiting and radiation of the pain to the right lower quadrant. A similar episode had occurred 1 year previously. On examination the patient did not appear acutely ill. The temperature was 102°F, the pulse 140, and the respirations 28. The abdomen was soft, with slight generalized tenderness referred to the right lower quadrant and maximum direct tenderness just below McBurney's point. There was slight rectal tenderness on the right. The white-cell count was 12,800 with 92 per cent neutrophils. Urinalysis showed a +++ test for albumin, with many coarse cellular casts and rare red cells per high-power field. The blood urea nitrogen was 9 mg per 100 cc, the blood Wassermann reaction was negative. In spite of the chronic glomerulonephritis and the atypical clinical picture, appendectomy was performed on the 2nd hospital day because of the persistence of spontaneous pain and tenderness. Acute appendicitis and lymphoid hyperplasia were found. The postoperative course was smooth, but characterized by persistent albuminuria and a blood pressure ranging about 150/80.

CASE 8* H C (M S H 450278), an 18-year-old Negro, was admitted to the hospital on December 23, 1939. For 2 years there had been an intermittent purulent discharge from the right ear. Stiffness of the right side of the face and drooping of the right side of the mouth had been increasingly more troublesome for the preceding 4 days. Several months previously the patient had worked for a short time at the Bronx Zoo. The temperature, pulse and respirations were normal.

Physical examination disclosed a well developed and well nourished man lying quietly in bed with eyes closed, head drawn back, legs extended and arms flexed. There was a coarse horizontal nystagmus on left lateral gaze, the eye

*This case was reported with special reference to the otologic features by Rosen.¹

grounds were not remarkable. A posterior marginal perforation of the right ear drum was present, with a small amount of thin, pulsating, nonfoul discharge, there was no tenderness over the mastoid process. The left ear drum was normal. Slight trismus was noted. Boardlike rigidity of the abdominal musculature was present, without tenderness. There was considerable increase in tone in the arms, and passive movement of the legs was difficult because of rigidity. The neck could not be flexed, but could be moved from side to side. The tendon reflexes in the arms were depressed, and those in the legs were decreased and jerky. No pathologic reflexes could be elicited. The patient was rational and talked slowly and carefully.

Shortly after admission the patient experienced a generalized, true tetanic convulsion, characterized by marked opisthotonos, without clouding of consciousness. Several such episodes occurred within a short period, each precipitated by noise or trauma, such as movement. A lumbar tap revealed clear spinal fluid under normal pressure, with normal dynamics, there were no significant cellular or chemical changes. The convulsive state soon became quite difficult to control, and almost constant opisthotonos was present. Extremely deep anesthesia was needed to obtain relaxation, and within a 5-hour period the patient received 70 mg. of Avertin per kilogram of body weight by rectum and 0.5 gm. of sodium amytal, and 100 mg. of Avertin per kilogram of body weight intravenously as well as deep ether anesthesia. Despite all sedation the rigidity persisted, and it was necessary to repeat the ether frequently. On the night after the practically permanent convulsive state, marked stridor developed, and artificial respiration was required several times. Because of extreme swelling of the tongue and episodes of laryngeal spasm, a tracheotomy was performed.

Large doses of tetanus antitoxin were administered intravenously—100,000 units a day for 2 days, followed by 50,000 units every other day, with a progressive reduction to 5000 units every 3 days. On the day after the onset of the convulsions the temperature rose to 104°F, the pulse to 140, and the respirations to 50 to 60, and the patient became incontinent. A bilateral bronchopneumonia, involving large portions of both lower lobes, was treated by 0.6 per cent sulfapyridine intravenously. The white-cell count rose from normal to 15,000, but a blood culture was negative. At the end of 5 days the patient's condition was still poor, with a temperature of 105°F and gasping respirations. Although the tetanic state was gradually being controlled, the treatment of the pneumonia was the chief problem, and the patient required an oxygen tent and constant special nursing care. At that time smears taken from the right ear were reported as showing a variety of organisms, including proteus and tetanus bacilli and the enterococcus. The pathogenicity of the tetanus bacilli was established by demonstration of their toxin-producing properties on bacteriologic investigation. There was a gradual recession of the rigidity, and the pneumonia slowly cleared. The temperature returned to normal, the tachycardia persisted, and there were occasional mild serum reactions.

A month after admission, while approaching convalescence, the patient developed abdominal cramps, without vomiting. The abdominal wall presented the extreme rigidity characteristic of tetanus, and there was localized tenderness over McBurney's point. In addition, there was evidence of mild serum sickness, with generalized lymphadenopathy and eosinophilia. Over a period of 12 hours' observation, the symptoms and signs persisted unchanged. The temperature remained normal. Examination of the blood showed a white-cell count of 14,900, with 68 per cent segmented, and 14 per cent nonsegmented neutrophils, 15 per cent eosinophils and 3 per cent monocytes, 8 days previously the count had been 11,300, with 44 per cent segmented and 8 per cent nonsegmented neutrophils, 31 per cent lymphocytes, 12 per cent monocytes and 5 per cent eosinophils. Despite the obvious reasons for possible temporizing in this case, operation appeared imperative once the diagnosis of acute appendicitis had been made. The patient was given 120 mg. of procaine as a spinal anesthetic, with no demonstrable relaxation of the abdominal musculature. The pathological report was "acute phlegmonous appendicitis."

Following recovery the patient underwent a modified right radical mastoidectomy, in an attempt to eliminate the primary focus of the tetanus. He was discharged from the hospital on March 4, and the tracheotomy was allowed to close.

Follow-up observation for 2 years showed him to be in good general health.

CASE 9 F L (M S H 501896), a 22-year-old man in good health, was admitted to the hospital on February 19, 1943, for the repair of a small, asymptomatic, right, indirect, inguinal hernia that had been detected in the course of a physical examination for induction into the Navy. There were no other physical defects. Urinalysis was negative, the white-cell count was 8300. On February 20, a right hernioplasty was performed under local (novocain) anesthesia. During the 1st week the postoperative course was uneventful, and the temperature at no time rose above 99°F. The patient was awakened at 4 o'clock on the morning of the 8th postoperative day with pain below the umbilicus, followed by nausea and unsuccessful attempts to vomit. The temperature was 97°F, and the pulse rate 60. The pain subsided in a short while, after the passage of flatus. Abdominal examination disclosed slight tenderness in the right lower quadrant, without spasm. There was no evidence of a wound infection. Under observation, slight pain recurred in the right lower quadrant, and the tenderness became more marked. The temperature rose to 99°F, the white-cell count to 12,800, with 90 per cent segmented and 3 per cent nonsegmented neutrophils. An appendectomy was performed 15 hours after the onset of symptoms. Pathological examination disclosed an acute phlegmonous appendicitis. Convalescence thereafter was without incident.

CASE 10 E Y (M S H 502446), a 10-year-old girl, was admitted to the hospital in March, 1943. Three years previously, following aspiration of an Indian nut, she had been treated at another hospital for "pneumonia," and a thoracotomy had been performed for empyema. The evidence of pulmonary suppuration had persisted. Shortly after admission a lobectomy of the left upper lobe, performed for numerous nonputrid pulmonary abscesses, was followed in 10 days by a drainage operation for empyema. On the 14th postoperative day the patient became nauseated and vomited several times, but there was no abdominal pain or tenderness. On the following day she was still nauseated, but did not vomit. She complained of periumbilical pain, and there was direct tenderness in the right lower quadrant. The pulmonary status contraindicated any surgery unless it was imperative.

An appendectomy revealed acute appendicitis. The patient withstood the operation well. Two weeks later a left hemiparesis developed, and death occurred on the day after operation for a large metastatic brain abscess secondary to intrathoracic suppuration.

These cases are not unique. They were selected, not from a review of the hospital records but from the large number of cases of acute appendicitis seen on an active surgical service over a three-year period. In common, they all represented appendicitis occurring in the course of other diseases.

The first 3 cases illustrate one of the most frequent problems concerned with abdominal symptomatology. Leaving aside the moot question of the relation between tonsillar (and upper respiratory) infection and acute appendicitis, the widespread distribution of upper respiratory infections during the winter months makes its coincidence with acute appendicitis inevitable in some patients. Although an unnecessary laparotomy performed on a patient with tonsillitis or an upper respiratory infection may contribute to the development of a more serious pulmonary complication, the consequences of neglecting an acutely inflamed appendix may be even more profound. Fever may be due to obvious nasopharyngitis or to a suspected appendicitis. The presence of a leukocytosis, as demonstrated either by the total white-cell count or by the differ-

ential count, is of no differential aid. Attention is called to the study of Medlar,² who in 1929 analyzed the variations in the white-cell counts of normal persons. In the series of 506 children with acute appendicitis reported by Scott and Ware,³ the white-cell count was below 10,000 in 17 children who presented perforation with peritonitis or abscess. In 1 case (M S H 497693), the white-cell count fell from 11,000 to 7500 in a patient with pain in the right lower quadrant and microscopic hematuria who was suspected of harboring a ureteral calculus, the disease was revealed at operation to be acute phlegmonous appendicitis. The current attitude of most surgeons on the subject of the white-cell count in the diagnosis of acute appendicitis may be summed up in Johnson's⁴ plea not to trust blindly to a low white-cell count as conclusive evidence against appendicitis, or to a high one as overwhelming evidence in favor of operation and by a similar statement in a review of cases of appendicitis in pregnancy by Twyman, Mussey and Stalker.⁵ In the presence of an acute upper respiratory infection the diagnosis of appendicitis must rest on clinical grounds.

The evaluation of abdominal pain in a person suffering from diabetes, cardiac disease, syphilis or nephritis involves many considerations. The point to be made is that these patients possess the same potentialities for developing acute appendicitis as other persons, episodes of abdominal symptoms and signs ordinarily suggestive of acute appendicitis should continue to be so regarded. Indeed, it can be contended with considerable justification that a patient suffering from a serious systemic disease has a far greater chance for survival if operated on in the uncomplicated than in the later stages of acute appendicitis. A similar situation exists in abdominal pain in the course of the contagious diseases of childhood. In the series reported by Goodman and Silverman,⁶ in more than half the cases of acute appendicitis, the appendix was found to have perforated at the time of operation. Delayed operation was at least in part attributable to an attempt to interpret the abdominal pain as a possible manifestation of the infectious disease. The difficulty of establishing an early diagnosis in young children is further attested by Scott and Ware,³ who point out that in children under six years of age perforation was encountered more than twice as often as simple acute appendicitis without rupture.

In the case of tetanus (Case 8) presented above, many unusual medical and otologic features were evident and the abdominal rigidity rendered the diagnosis of an acute intraperitoneal inflammatory process difficult. In the patient convalescing from

a right-sided hernioplasty performed a week previously (Case 9), careful consideration had to be paid both to the site and to the circumstances of the first operation. Case 10 illustrates the occurrence of acute appendicitis in the course of unrelated pulmonary suppuration.

Acute appendicitis has been recorded in the course of acute anterior poliomyelitis,⁷ Addison's disease⁸ and pneumonia with malaria.⁹ Although regarded as unusual among the newborn and the aged, acute appendicitis has been reported in a sixteen-day-old infant.¹⁰ And with the increase in the life expectancy of the population, more and more cases in the older age groups are encountered.

It is an established surgical principle that the possible complications of acute appendicitis can best be avoided by prompt appendectomy during the early period of the inflammatory process. The favorable influence of the sulfonamides and newer chemotherapeutic agents on the prognosis in the severer forms of acute appendicitis cannot be advanced as a valid argument for temporizing. A short interval from the onset of the symptoms and signs of acute appendicitis is still the optimum time of operation, and this principle cannot be compromised because acute appendicitis may occur during the course of other diseases.

SUMMARY

Ten representative cases of acute appendicitis occurring in the course of other diseases are presented.

The tendency to interpret such cases as possible manifestations of the underlying disease rather than as an independent intraperitoneal lesion is pointed out. The consequences of a temporizing attitude in terms of the increased morbidity of appendiceal peritonitis is discussed.

Acute appendicitis must be diagnosed on the basis of clinical evidence (symptoms and signs) regardless of any coexisting disease.

ASIATIC SCHISTOSOMIASIS*

Report of an Early Case

LYMAN O WARREN, JR., MD†

BOSTON

THE following case of acute Asiatic schistosomiasis was unique in that an opportunity was afforded to follow the clinical course with repeated sigmoidoscopies and serial roentgenograms from the onset of symptoms to the termination of a course of treatment—a period of sixty days. More informative accounts of the disease are given by Billings, Winkenwerder and Hunninen,¹ Thomas and Gage,² Faust et al.³ and others.⁴

A 19-year-old soldier of Italian descent was admitted to the 117th Station Hospital on Leyte, Philippine Islands, on December 19, 1945, with a chief complaint of "hives." He stated that about 30 days previously he had been exposed to the infected waters of a tributary of the Palo River and immersed from feet to waist for about 3 hours. He had noticed no swimmers' itch during the next 48 hours and had felt entirely well until the onset of urticaria 2 days before admission. The past history was essentially unremarkable except for an attack of urticaria 5 years previously when the patient had been living in New York City. The family history was negative for allergic diseases.

Physical examination disclosed giant urticarial lesions of the face, torso and extremities. The spleen and liver were just palpable on deep inspiration, and both organs were firm and not tender. The remainder of the physical examination was negative.

During the 1st week in the hospital urticaria was intermittent and associated with angioneurotic edema of the right cheek and infraorbital tissues and the dorsum of the right foot. These lesions cleared after 8 days and did not recur. The white-cell count, which on December 21 was 9850, with 6 per cent eosinophils, on December 26 was 6250, with 10 per cent eosinophils. Sigmoidoscopy on the day after admission showed no nodular lesions of the rectosigmoid region characteristic of schistosomiasis.

On December 24 the temperature, which had been normal, rose to 102°F, with a proportionate elevation of the pulse. Other complaints were anorexia, nausea and moderately severe colicky epigastric pain, which remained troublesome for the next 3 weeks. The temperature and pulse remained intermittently elevated for 24 days, the temperature varying between normal and 103°F, and the pulse between 70 and 120.

On December 25 a dry cough developed and was associated with sibilant rhonchi and a few fine crepitant rales in both lungs. An x-ray film of the chest taken on December 27 showed multiple patches of increased density scattered throughout both lung fields, with increased prominence of the bronchovascular markings.† Concentrated stool specimens on December 31 and January 2, 3 and 4 were guaiac negative. On January 5 a repeated chest plate showed a definite change in the distribution of the areas of increased density.

On January 3 sigmoidoscopy for the first time revealed disease of the rectosigmoid. Several distinctly erythematous areas and erythematous nodular lesions measuring 1 or 2 mm. in diameter were visualized. The nodules did not have the yellow color ascribed to typical lesions of schistosomiasis and did not offer the characteristic resistance with clicking sensation to the lip of the sigmoidoscope. A smear of mucus taken from the surface of one of the nodules was negative

for ova. Concentrated stool specimens were negative for ova on January 5 and 7. Cysts of *Entamoeba histolytica*, however, were found on the latter date and again on January 8. Sigmoidoscopy was repeated on January 9, and ten to twelve nodular lesions, similar to those previously observed, were visualized in the same region of the rectosigmoid. The nodules, which were more prominent and offered resistance to the lip of the sigmoidoscope in the typical fashion, were still red. A few pinpoint erythematous lesions were considered typical of amebiasis. A biopsy specimen of one of the nodules was negative on direct examination, probably because a deep enough bite had not been taken.

In the meantime, the patient was running a fever, complaining of severe pains in the upper abdomen and right upper quadrant. There was some increased tenderness of the liver edge to palpation, and the area of liver dullness had become tender to light percussion. On January 7 the white-cell count was 20,150, with 64 per cent neutrophils, 14 per cent eosinophils and 22 per cent lymphocytes. Although a diagnosis of schistosomiasis japonica seemed likely, it was considered advisable, in the lack of definite proof, to try a 6-day course of emetine hydrochloride to evaluate the effect of amebic infection on the liver symptoms and the fever. There was no response of temperature or symptoms to emetine. A chest plate on January 11 showed some increase in the patchy nodular lesions in both lung fields without significant change in the bronchovascular markings.

On January 14 sigmoidoscopy was repeated, and the nodules for the first time had a distinctly yellowish or whitish-yellow color, a narrow erythematous base being observed in some of them. With the use of a more suitable biopsy forceps one of the nodules was excised and examined microscopically in a drop of saline. Clusters of ova of *Schistosoma japonicum* were seen. Examination of the blood showed a red-cell count of 4,900,000, with a hemoglobin of 14 gm (Sahli), and a white-cell count of 35,000, with 40 per cent eosinophils.

On January 15 a course of antimony potassium tartrate was begun. A fresh 1 per cent aqueous solution was prepared on each day of treatment and within ½ hour prior to injection, 0.5 gm of the drug being dissolved in 50 cc of sterile distilled water under aseptic precautions, no attempt was made to sterilize the solution after it had been prepared. From this solution the appropriate dose was withdrawn and incorporated in 1000 cc of 5 per cent dextrose in physiologic saline, for slowness of injection and a reduction of local irritating effects. The drug was given on alternate days, beginning with 40 mg (representing 4 cc of the 1 per cent solution) and increasing the dose by 20 mg each time until 140 mg (14 cc) had been reached, this dose was not exceeded for the remainder of the course. A total of 18 gm was given in fifteen injections over a period of 31 days. It was considered advisable to postpone the twelfth injection because of rather severe upper abdominal pains on the preceding day. Instructions had been left with the nursing staff to discontinue the intravenous injections if nausea, vomiting, upper abdominal pain, a sense of constriction or pain in the chest, stiffness of the muscles, bradycardia or a drop in the blood pressure occurred. One and a half hours were allowed for the intravenous injection, and the patient was kept in bed for 1 hour after each treatment. Physical examinations were made daily, blood pressures were taken twice a day, the urine was examined every other day and electrocardiograms were taken once a week at another hospital. Fluids were forced to prevent possible kidney damage from the drug, and the intake and output were recorded. A high-carbohydrate, high-protein diet with added vitamins was given to guard against liver damage. No serious toxic reactions were observed.

Clinically, improvement began early. After the second injection the temperature became normal and remained so thereafter except for a transient elevation from an upper

‡Reproductions of this and subsequent roentgenograms will be included in the reprints of this paper.—Ed.

respiratory infection. The appetite improved gradually, and the weight lost in the early part of the illness was regained. Only one positive stool was reported, and this was obtained on the day after the first dose of antimony potassium tartrate. On this occasion numerous ova were seen, consisting generally of mature forms containing actively motile miracidia. The spleen and liver were no longer palpable after January 29. A chest plate on February 16 showed less infiltration in both lung fields, although the hilar markings were still accentuated to the same extent as before. The white-cell counts on January 26 and 29 were respectively 20,550, with 40 per cent eosinophils, and 11,000, with 43 per cent eosinophils, whereas on February 4, 8 and 14 they were 9000, with 60 per cent eosinophils, 12,800, with 31 per cent eosinophils, and 7300, with 30 per cent eosinophils. Sigmoidoscopic evidences of improvement began as early as February 1, and by February 15 there was still further improvement, so that the nodules might readily have been missed had their previous location not been known. On February 16 the patient was transferred, greatly improved, to a general hospital for evacuation to the United States.

DISCUSSION

Several features of this case deserve comment. In the first place, the failure of laboratory tests to demonstrate ova in the stools is not infrequent, in spite of refined concentration technics. Only one positive stool specimen was obtained during the patient's hospitalization, and that on the day following the first dose of antimony potassium tartrate, when the stool became heavily laden with ova. This may have been simple coincidence, but was more probably due to the provocative action of the drug on the gravid female worms, causing them to expel their eggs at one time. A somewhat analogous reaction is seen in malarial infections, in which the blood smear may not become positive until after a dose of quinacrine (Atabrine), when a heavy infection may become manifest.

Sigmoidoscopy has received attention as providing valuable diagnostic aid following a report by Johnson and Berry⁵ that yellowish nodules of the upper rectal and rectosigmoid mucosa were characteristic of Asiatic schistosomiasis. From these nodules or pseudotubercles, which occur singly or in clusters, nests of ova can be removed with a simple biopsy forceps. Although we were aware of this diagnostic feature the diagnosis was not made because at first no pseudotubercles could be found and subsequently small, red macules and elevated lesions were observed from which no ova could be obtained. So far as we know, this is the first reference to the initial appearance of the yellow nodules of Johnson and Berry, with the lapse of eleven days, however, there was no mistaking their nature—the greater elevation, sense of firmness to the tip of the sigmoidoscope and yellowish color were all characteristic, and biopsy findings at this stage were merely confirmatory.

The serial roentgenograms of the chest were also interesting. Such films are not in themselves pathognomonic, presenting the picture of bronchopneumonia, but their association with urticaria, angioneurotic edema, leukocytosis, eosinophilia, fever and abdominal pain with liver tenderness should be

considered strongly suggestive of schistosomiasis and should point to the advisability of repeated examinations of the stools and sigmoidoscopy. The pulmonary infiltrations have a doubtful pathogenesis. It is not known whether the roentgenologic picture represents a reaction of the lung parenchyma to ova transported from the mesenteric venules via the portal circulation and liver or to adult worms living in the lungs or to their ova deposited there. In fatal cases of Egyptian schistosomiasis with pulmonary involvement, adult worms have been found in the arteries of the lungs. It would not be at all surprising if adult worms of *S. japonicum* also develop in the lungs and that the eggs when present are the product of the worms located there. In this respect it is interesting to note that the same problem arises to explain the nature of cerebral schistosomiasis, in which ova have thus far been found only in the brain substance, with no evidence of the presence of adult worms.⁶

Attention is called to the complete lack of effect of 0.4 gm of emetine given for six days. The drug was administered because of the possibility that some of the symptoms were due to an amebic hepatitis, although it was not expected to be of great value. Older authorities had stated that the drug had some schistosomicidal effect, but none was demonstrated with the small amount used in this patient. In marked contrast was the gratifying symptomatic and objective response to antimony potassium tartrate. Although two potential myocardial depressants were used in this case, no evidences of cardiac damage were detected.

SUMMARY

An early case of Asiatic schistosomiasis is reported.

The characteristic yellowish nodules of the rectosigmoid and upper rectum were shown to have an earlier stage in which they have a distinctly red color and are smaller and less resistant to the sigmoidoscope than they are in the later course of their development. The diagnostic value of sigmoidoscopy is confirmed.

Serial roentgenologic findings are presented that may have represented a reaction of the lung parenchyma to ova or adult worms of *Schistosoma japonicum*.

The effectiveness of antimony potassium tartrate (tartar emetic) in this case was demonstrated.

MEDICAL PROGRESS

THE PHYSIOLOGIC AND CLINICAL SIGNIFICANCE OF PLASMA PROTEINS AND PROTEIN METABOLITES*

JACK METCOFF, M.D.,† AND FREDRICK J STARE, M.D.‡

BOSTON

PROTEIN is an essential component of protoplasm. Both structure and function of body tissues are dependent on specific proteins, such as enzymes and hormones. Fluid balance, hemostasis, many hormone and lipoprotein complexes and certain immune mechanisms are related to protein nutrition. Recent observations derived from many sources have re-emphasized and extended the clinical significance of plasma proteins, protein metabolites and protein degradation products. The concept of constant interchange or "dynamic equilibrium" between the proteins of blood and other tissues,^{1,2} the elucidation of indispensable amino acids,^{3,4} the application of heavy nitrogen and marked carbon to problems of nitrogen metabolism and immunology⁵⁻⁷ and the adaptation of physico-chemical technics — for example, electrophoresis — and fractionation procedures to plasma proteins⁸⁻¹¹ are fundamental contributions to better clinical understanding of plasma protein significance. The significance, characterization and function of various circulating plasma proteins and protein metabolites, the evaluation of protein abnormalities and the general interrelations of amino acids, protein synthesis and nitrogen metabolism are considered in this paper.

CIRCULATING PROTEINS

The modern technic of electrophoresis, as developed by Tiselius,⁸ affords a means of characterizing plasma proteins. This procedure depends on the application of an external electric field of force to charged protein molecules dissolved in a suitable solvent. Under such conditions, proteins move in one direction in acid solutions and in the opposite direction in alkaline solutions. Thus, in an apparatus providing a given electromotive field strength acting on proteins dispersed in a salt solution, movement of the protein is determined by its physical properties and the hydrogen ion concentration, the molar concentration and the nature of the solvent. Since different components of a protein aggregate usually move with different velocities, it is possible to distinguish several components within a com-

plex protein aggregate such as plasma. Specialized refractometric optical systems, which project a shadow (*Schlieren*) pattern of the migrating protein on a photographic screen, afford a permanent record of electrophoretic mobility. Both the characteristic rate of motion, which determines the probable protein component, and the apparent relative concentration of that component may be calculated from the *Schlieren* pattern.¹²

Analyses of human plasma by modifications of this method have postulated at least six electrophoretic components: albumin, alpha-1, alpha-2, beta and gamma globulin and fibrinogen.¹²⁻¹⁶ (Fig. 1) Fractionation studies have indicated their distribution in plasma (Table 1). The conventional sodium sulfate "salting out" method of Howe,²¹ which precipitates fibrinogen, euglobulin and pseudoglobulins I and II at increasing molar concentrations, affords a somewhat different distribution (Table 1). Similarly, other methods, including ultracentrifugal sedimentation, osmotic pressure and viscosity, that depend on heterogeneous physical and chemical properties of protein, such as size, shape and electrical charge, provide diverse plasma protein distributions. Determination of plasma protein components by electrophoresis differs from the more familiar chemical method in yielding more complete fractional resolution, which particularly minimizes the overlap of albumin and the various globulins. Sodium sulfate fractionation, for example, appears to assign approximately 5 per cent more nitrogen (31 per cent more protein) to the albumin fraction than indicated by electrophoretic technics.²² Accordingly, electrophoretic albumin-globulin ratios tend to be lower, (about 30 per cent) than the chemically determined equivalent.¹⁶ The more precise data from electrophoretic analyses of plasma should provide a supplemental, somewhat more readily interpreted, body of experimental and clinical findings. Extensive data derived from electrophoretic analyses of plasma in health and disease are rapidly becoming available.

Alterations in plasma protein concentration with age, sex, race, health and disease are well known. Normal ranges^{18, 19, 23, 24} are denoted in Table 2. Deviation from these values occurs in many diseases. Hypoproteinemia, usually reflecting a depletion of the albumin fraction, is more frequent clinically than hyperproteinemia, which usually represents

*From the Department of Nutrition, Harvard School of Public Health, the Department of Biological Chemistry, Harvard Medical School, the Medical Clinic, Infants' and Children's Hospital, and the Medical Service, Peter Bent Brigham Hospital.

†Research fellow, Department of Nutrition, School of Public Health and Department of Biochemistry, School of Medicine, Harvard University.

‡Associate professor of nutrition, Harvard Medical School and Harvard School of Public Health, associate in medicine, Peter Bent Brigham Hospital.

an increase in one or several of the globulin components of plasma. Diseases in which hypoproteinemia or hyperproteinemia may occur are listed in Table 3.

The clinical significance attending alterations in each of the various plasma protein fractions is not completely clear. Some pertinent observations, however, have been made.

Serum albumin is the most important circulating protein for maintenance of colloid osmotic (oncotic) pressure of the blood. Constituting approximately 55 to 60 per cent* of plasma protein, it is responsible

appears to increase in relation to plasma volume and surface area until maximal values are approximated coincident with puberty (see Tables 2 and 5). Decreased serum albumin is most frequently the result of protein loss by leakage into extravascular spaces (trauma or shock, or both) into urine (nephrosis, chronic glomerulonephritis and so forth) or from wound surfaces (hemorrhage and burns), inadequate protein synthesis associated with extensive liver damage (cirrhosis or hepatitis) or altered hepatic function (concomitant to severe anemia, chronic nephritides, various infections and so forth), inade-

FIGURE 1 A Typical Electrophoretic Pattern of Human Plasma

This diagram was derived from analysis of a 2 per cent solution of pooled normal human plasma in a sodium diethyl barbiturate buffer (pH 8.6) and an ionic strength of 0.1. It was kindly furnished by Dr S. H. Armstrong, Jr., of the Department of Physical Chemistry, Harvard University.

for about 80 per cent of the oncotic pressure.²⁷ Its small size (molecular weight, 70,000) and relatively larger net charge account for an osmotic effect greater than that exerted by combinations of the various globulins (molecular weight, approximately 170,000 to 180,000). Serum albumin apparently attains maximal (adult) concentration at approximately one year of age^{18, 24}; electrophoretically observed albumin concentrations of maternal and fetal plasmas, however, appear to be similar.²⁵ The quantity of circulating protein, including albumin, ap-

*Present estimates are somewhat lower: 52 to 55 per cent.

quate dietary protein intake, and increased utilization or decreased absorption of protein. Increased protein utilization occurs when metabolism requires burning of protein for energy if supplies of carbohydrate and fat are inadequate to support caloric needs. This may ensue when parenteral amino acids, plasma and electrolyte replacement therapy are administered without supplying caloric requirements in the form of glucose or fat, when increased protein and caloric demands are not met in various acute and chronic diseases, such as typhoid fever, hepatitis, tuberculosis and hyperthyroidism, or

when the heightened metabolic demands of rapid growth, pregnancy and lactation are confronted with relative protein and caloric inadequacy. Decreased absorption of protein is primarily associated with gastrointestinal abnormalities, including diarrhea, specific mucosal or intestinal vascular disease and surgical stomas of the small bowel.

Depletion of plasma protein, — specifically, albumin, — usually associated with a decreased plasma volume, probably represents a much more extensive depletion of tissue protein^{1, 34, 35}. Thus, reversal of hypoalbuminemia with associated replenishment of tissue protein understandably requires consider-

The albumin fraction appears to serve other functions of clinical interest. Partial binding of the sulfonamide drugs to albumin may account for their distribution in body fluids, solubility in plasma and decreased bacteriostatic activity³⁷. The dye T-1824, used in the clinical determination of blood volume, is bound by albumin and migrates with it in the electrophoretic field. Its disappearance from plasma appears to be related to the rate at which albumin escapes³⁸. It has been reported that normal or abnormally occurring albumin fractions may inhibit the colloidal gold reaction,^{39, 40} cephalin-cholesterol flocculation⁴¹ and sedimentation rate⁴². Subsequent

TABLE 1 *Distribution of Human Plasma Protein Components in Normal Adults as Determined by Electrophoretic and Sodium Sulfate Fractionation*

ELECTROPHORETIC FRACTIONATION*			SODIUM SULFATE FRACTIONATION		
COMPONENT	PERCENTAGE OF TOTAL PROTEIN†	CONCENTRATION gm./100 cc	COMPONENT	PERCENTAGE OF TOTAL PROTEIN†	CONCENTRATION‡ gm./100 cc

Total	45	2.71-2.72	Total globulin	33	1.9-3.3

*The distribution of components in normal pooled human plasma as derived from electrophoretic analysis is based on the total refractive increment contributed by each component. The quantitative amount of each fraction is based on nitrogen analysis assuming the conventional conversion factor of 6.25. A further assumption tentatively assigns a similar refractive increment per gram of nitrogen to all components.¹¹ Data derived from several studies.^{9, 11, 16, 17} Fractionation in diethylbarbiturate buffer at pH 8.6.

†Percentage of total protein represents an approximation.

§Data from Cantarow and Trumper.²⁰

able quantities of protein or albumin. With sufficient reduction of serum albumin and resultant diminution of plasma oncotic pressure, edema is likely to occur. The occurrence of edema, however, is modified by hydration, electrolyte (particularly sodium) concentration, tissue pressure, lymph flow, capillary permeability, extracellular fluid pressure, adrenocortical and gonadotropic hormones and so forth. It has been stated that the critical plasma concentrations below which edema occurs is approximated by a total protein of 5.5 gm per 100 cc, an albumin level of 2.5 gm per 100 cc and a plasma specific gravity of 1.023.³⁶ Clinical aberrations from this observation are numerous, as might be expected, since protein concentration measurements afford an inadequate indication of the oncotic effect exerted by the total circulating protein and many associated factors further modify the occurrence of clinical edema. Recent evidence questions the validity of Starling's generally accepted oncotic equilibrium theory and suggests the inadequacy of a simple hypoproteinemic causation of such a well known clinical entity as famine edema.³⁶

unpublished data on fractionation have put these activities in small alpha-1 globulin impurities.⁴⁴

Albumin, as a product of plasma fractionation, has considerable clinical value in the therapy of hemorrhagic, traumatic or burn shock.⁴⁴⁻⁴⁶ It is chiefly useful in rapidly restoring the diminished plasma volume toward normal at the expense of extravascular fluids.⁴⁷ Albumin has also seemed efficacious in the treatment of severe malnutritional hypoproteinemia occurring in adults⁴⁴ and infants,⁴⁵ in nephritis^{17, 48} and in cirrhosis.⁵⁰

Hyperproteinemia, not the result of decreased plasma volume, is usually synonymous with hyperglobulinemia — an increase in one or several globulin fractions. Extensive data pertaining to alterations in the various electrophoretic globulin fractions are not yet available. Globulins have been reported to attain maximal (adult) concentrations by the fourth year of life.¹⁸ Alpha-1 globulin may be closely associated clinically with the electrophoretically appositional albumin, since it appears to exert a similar effect on oncotic pressure⁵¹ and to resemble albumin in its plasma clearance.⁴⁹ Alpha-1 and alpha-2

globulins occur in lower concentrations in fetal than in maternal plasmas.²⁵ Increased alpha globulins have been reported in a variety of diseases^{7, 49, 50, 52-55}. The significance of these observations is unknown. It has been suggested that the depletion of plasma albumin may be reflected by a compensatory increase of alpha globulin in liver disease,⁵² malnutrition, tuberculosis and carcinoma⁵⁶ or, conversely, that hyperglobulinemia prompts an equilibrium fall in albumin.⁵⁷

Beta globulins are carriers of lipid components and, with the alpha globulins, constitute the lipoproteins of plasma.^{12, 58} Approximately two thirds of the total plasma cholesterol appears to be asso-

Relatively purified plasma fractions composed largely of beta and gamma globulins have been prepared as specific isohemagglutinins with anti-A and anti-B activity.⁶² These fractions have been found clinically acceptable as standardized blood-grouping serums.⁶²

Since immunologic mechanisms are partially dependent on antibody response and many antibodies are related to gamma globulin, considerable interest has centered about electrophoretic demonstrations of relative changes in the gamma-globulin fraction of plasma. Antibodies reacting with diphtheria toxin, streptococcal erythrogenic toxin, influenza A virus, mumps virus and the H antigen of *Eberthella*

*No significant variation with sex, but some racial variation

†Values obtained are somewhat variable depending on technique of determination. Most of the reported total protein values are derived from micro-Kjeldahl analyses, and the albumin and globulin from sodium sulfate fractionation.

‡Albumin may vary somewhat with the season. The variation may be a manifestation of seasonal blood volume changes.¹⁸

§Indicates mature level attained

ciated with beta globulin. Over half the carotene and phospholipids are also concentrated with the alpha and beta globulin fractions. Prothrombin appears to be a beta globulin.¹² The thymol-turbidity reaction appears to be related to alpha and beta globulins.⁴¹

Demonstrable increases in beta-globulin components of plasma have been reported in association with several diseases^{13, 14, 17, 49, 50, 52-56, 58-61} and in maternal plasma at parturition.²⁸ The observed increase appears to depend on abnormally large amounts of lipoids, which migrate with the beta and alpha fractions. The refractometric error introduced by the plasma lipoids in such diseases subjects calculation of the plasma concentration of a given electrophoretic protein component to considerable error.⁶⁰

typhosa have been immunologically demonstrated in the gamma-globulin fraction.⁶⁴ The concentration of these antibodies was some fifteen to thirty times that in pooled plasma. All antibodies, however, are not contained in the gamma-globulin fraction of plasma. The O antibody of *E. typhosa*, for example, appears to be associated electrophoretically with beta and possibly alpha, as well as with gamma globulin. Similarly, all gamma globulin is not antibody.⁶⁵ The presence of antibodies⁶⁶ and normal serum gamma globulin in lymphocytes⁶⁷ indirectly supports the concept of the extrahepatic origin of globulin. Antibody release from lymphocytes, attended by an increased serum gamma globulin, may be mediated through pituitary-adrenocortical control.⁶⁸

Clinical evidence pertaining to the change in gamma globulin is somewhat less striking than inference from immunologic data suggests. In relation to infant immunity it is interesting that the gamma-globulin concentration of fetal plasma, determined from placental blood at birth, is considerably greater than that occurring in the parenteral maternal plasma.²⁸ Gamma globulin has been

to that of gamma globulin.⁷⁰ Gamma globulin may be diminished in chronic malnutrition associated with hypoproteinemia.^{56, 71} This observation is particularly interesting in view of the possible relation of protein deficiency to impaired antibody production.⁷² Gamma globulin appears to be largely responsible for positive colloidal gold and cephalin-flocculation tests.⁴⁰ It has no effect on the thymol-

TABLE 3 Conditions Associated with Alterations in Plasma Protein Concentration *

HIGH CONCENTRATIONS		LOW CONCENTRATIONS	
General		General	
Usually associated with dehydration and with increased globulin which are frequent in diseases of reticuloendothelial system and in chronic infections		Usually associated with mechanical loss of protein by extravasation or renal excretion or with decreased albumin formation as result of malnutrition or liver disease	
Specific		Specific	
Dehydration		Physical loss of plasma proteins from circulation	
Insufficient fluid intake		Hemorrhage acute or chronic and blood dyscrasias	
Fluid loss		Weeping wounds or skin lesions (burns)	
Intestinal obstruction and fistulas		Shock surgical and traumatic	
Diarrhea especially in infants and also cholera and dysentery		Kidney disease with albuminuria	
Vomiting		Nephrosis	
Severe diabetic acidosis		Chronic glomerulonephritis	
Intense heat and exertion		Amyloidosis	
Addison's disease			
Shock, surgical and traumatic		Malnutrition (low albumin)	
Burns, first few hours (in some cases)		Dietary inadequacy in chronic infections	
Pulminant infections		Low-protein diet	
Diseases involving reticuloendothelial system (high globulin)		Incomplete absorption, as in sprue and celiac syndrome	
Multiple myeloma		Cancer of stomach and pancreas	
Leukemia		Pernicious anemia	
Liver cirrhosis and cancer		Diabetes mellitus unregulated	
Acute hepatitis		Hyperthyroidism	
		Toxemia of pregnancy	
Chronic infections (high globulin)			
Acute nephritis		Conditions with retarded albumin synthesis presumably because of liver damage (low albumin)	
Ulcerative tuberculosis		Cirrhosis and cancer of liver	
Syphilis		Chronic poisoning (benzene phosphorus and so forth)	
Lymphopathia venereum		Hepatitis, chronic	
Subacute bacterial endocarditis		Hepatorenal syndrome	
Acute disseminated lupus erythematosus			
Periarteritis nodosa			
Rheumatic fever			
Rheumatoid arthritis			
Boeck's sarcoid			
Leprosy			
Kala-azar			
Schistosomiasis			
Filariasis			
Trypanosomiasis			
Chronic suppurative infections			
Pyelonephritis			
Pyonephrosis			
Gangrene associated with diabetes mellitus			
Malaria			
Tuberculosis			

*Modified from Kagan²⁵ and from Phillips et al.²⁶

reported as increased in scarlet fever — the increase appearing to be associated with increased titer of antistreptolysin O³⁴ — and in relapsing malarial infection with *Plasmodium vivax* associated with paroxysms.⁵³ An increase in this fraction has also been noted in association with acute nephritis, acute rheumatic fever, periarteritis nodosa,^{17, 55} lupus erythematosus⁵⁹ and various subacute and chronic infections.⁵⁵ A nonspecific increase in gamma globulin has been observed in various types of myeloma^{13, 55} and chronic hepatic disease.^{50, 52, 55} The Wassermann antibody appears to be associated with the gamma-globulin fraction, having an electrophoretic mobility between beta and gamma components and a sedimentation constant similar

turbidity reaction,⁴¹ and may inhibit the sedimentation rate,⁴² although in particular cases an accelerated sedimentation rate is apparently related to gamma-globulin increase.⁵⁵

The clinical administration of relatively purified gamma globulin has proved efficacious in the prevention and attenuation of measles^{73, 74} and in the prophylaxis of infectious hepatitis^{75, 76} and mumps orchitis (if the gamma globulin is derived from mumps convalescent serums).⁷⁷

Fibrinogen, the last of the currently isolated major plasma protein components, appears to undergo little fluctuation with growth and health.¹⁸ It is primarily concerned with the blood-clotting mechanism. Fibrin has been isolated, purified and

adapted to clinical use^{9, 12} Fibrinogen concentrations may be increased in a variety of conditions acute infections, malaria, pregnancy and menstruation and following roentgen irradiation,⁷⁸ nephrosis and cirrhosis^{17, 50, 55} Presumably, a relatively large proportion of protein* having an electrophoretic mobility similar to fibrinogen is a beta globulin not

several of the globulin fractions⁵⁵ Decreased plasma fibrinogen has been reported in association with several diseases, but normal concentrations are low and variations are large, hence, the deviations are difficult to interpret Sodium sulfate precipitation of fibrinogen, generally used, may precipitate some of the fibrinogen with globulin and may further

*Data pertaining to physiologic function and abnormal variations of the specific plasma protein components are at present, quite limited Subsequent data will undoubtedly extend clarify or modify those indicated in this table

†The concentration of the principal protein components in the various fractions denoted as percentages is derived largely from data of Cohn and Strong Hughes, and Armstrong¹² and subsequent reports from the Department of Physical Chemistry Harvard Medical School Fractions denoted by Roman numerals refer to that portion of the plasma protein precipitated from an alcohol-water solution of known concentration ionic strength and pH at very low temperatures The precipitates are subsequently dried, purified and analyzed for protein components by electrophoretic techniques Several electrophoretic components may be concentrated in any one fraction Six major fractions (I-VI) and seven subfractions have been evolved by various procedures to date Fractions II and III are precipitated together in several methods

‡Many of the factors that appear to be concentrated in Fraction II plus III have not been specifically isolated or purified others as yet undemonstrated, may occur in these or other fractions

§The increase is represented largely by alpha-2 globulin

specifically related to the blood-clotting function¹¹ The sedimentation rate of erythrocytes may be related to fibrinogen,⁴² presumably being proportional to the amount of so-called "contractinogen" it contains⁷⁹ Recent evidence, however, suggests that the elevated sedimentation rate occurring in many conditions may also be related to one or

impair interpretation¹⁸ Reported physiologic functions of the plasma protein components and electrophoretic variations occurring in association with several diseases are summarized in Table 4

Observations pertaining to pathologic variations in albumin and globulin have repeatedly indicated that numerical expression of the albumin-globulin

ratio provides little insight into specific alterations in albumin or globulin fractions^{18, 24, 26, 80} Used as a diagnostic aid, the ratio may be quite misleading in nephrosis, a decreased albumin-globulin ratio is dependent on depleted albumin and probable, relative increases in alpha and beta globulins, and in cirrhosis, on depleted albumin, increased fibrinogen and gamma globulin, in malnutrition, it probably depends on depleted albumin and relatively increased alpha globulin, in pregnancy it may be dependent on hemodilution of albumin, with a relative increase in fibrinogen, and in chronic infections, it depends on an unchanged albumin and increased beta-globulin and gamma-globulin frac-

volume^{34, 83-86} Thus, a protein concentration of 6 gm per 100 cc in a patient with a total plasma volume of 2000 cc represents a significantly different amount of circulating protein than that occurring in another person of similar size, also with a total protein of 6 gm per 100 cc but a plasma volume of 1000 cc Such a hypothetical case indicates a difference of 60 gm (50 per cent) in the total circulating plasma protein This difference is masked by the relatively unphysiologic consideration of concentration alone — for as Peters⁸⁰ has pointed out, a three-dimensional function cannot be evaluated by two-dimensional measurements, and alter-

†All children within anthropometric norms

‡Total circulating protein values derived from average plasma volume data and average plasma protein concentrations noted in Table 2 tabulated values are averages and do not include standard deviations

§Total circulating protein = total protein (gm per 100 cc.) — 100 x total plasma volume (cc)

tions Albumin is synthesized principally in the liver, whereas globulin may be synthesized extra-hepatically^{67, 81} The amino acid compositions of albumin, gamma globulin, beta globulin and fibrinogen differ⁸² Since the origin, structure and function of albumin and globulin differ and the various globulin fractions have further structural and functional differences, it is evident that these fractions, determined with total protein concentrations, should be considered individual variables The albumin-globulin ratio, therefore, as generally used has little significance and frequently leads to confused clinical interpretations

Hypoproteinemia and hyperproteinemia, by usage, refer to the quantity of protein dissolved in an arbitrary amount of plasma Since the volume of circulating plasma is subject to considerable change in relation to growth, health and acute and chronic disease, it is evident that significant changes in quantities of circulating plasma protein may be masked if the protein concentration is measured without regard for expanding or contracting blood

tions in total circulating protein and plasma volume cannot be estimated accurately from total protein concentrations^{85, 86}

Plasma-volume alterations are not static phenomena As a phase of the total extracellular compartment, plasma-volume change is subsequent to factors altering water balance Changes in plasma volume have a temporal significance — for example, *relative* to the previously existing plasma volume in a given patient or *absolute* in regard to a previously normal plasma volume Altered concentrations of circulating plasma components may be masked by either an increased or a decreased plasma volume Plasma protein and electrolyte concentrations, therefore, may be more relative than absolute An increased plasma volume is most frequently dependent on one or several factors altered renal function or sodium retention, or both, increased plasma bicarbonate, with altered carbon dioxide and oxygen tensions, and an increased basal metabolic rate, and decreased circulating cell volume

and hemoglobin. Decreased plasma volume usually derives from several factors: increased sodium and chloride loss, decreased plasma bicarbonate, with altered carbon dioxide and oxygen tensions, albumin depletion, water and salt deprivation, severe fluid loss, with dehydration, and frank plasma loss. The first three factors primarily alter osmotic equilibria, they may be associated with abnormal

volume. A simple method of estimating blood volume from change in blood specific gravity following plasma infusion has been reported.⁹¹

It is to be hoped that consideration of the more fundamental concept of circulating proteins per unit of plasma volume will gradually supersede the often confusing two-dimensional measurement of plasma protein concentration. To this end, normal

*Blood volume is altered in many conditions. In some cases a variation in the total red-cell volume is more significant than alteration of plasma volume as in chronic anemia and polycythemia. This table is confined to states in which plasma-volume changes have been observed and recently reported. Most frequently several conditions concurrently occur to modify plasma volume. The resultant of these influences determines the direction of plasma-volume change. The groupings as tabulated therefore are resultant expressions of various influences. Accordingly the various pathologic processes are somewhat inadequately tabulated under a single heading. When other associated conditions significantly modify the reported deviation they are indicated by the appropriate ipsilateral Roman numeral or letter or both, in parentheses.

renal function. Abnormal renal function may supervene, in association with peripheral vascular collapse.

Clinical measurements of the plasma volume are usually accomplished by injecting a given amount of an azo blue dye, T-1824, and determining the concentration (dilution) of dye in several plasma or serum samples obtained at stated intervals after injection. From these data, the plasma volume may be calculated.^{87, 88} A simplified technic, employing injection of a fixed amount of dye with subsequent withdrawal and analysis of a single blood sample at a given time thereafter, has been reported.^{89, 90} This modification provides a practicable clinical method for determining plasma

values and an incomplete tabulation of plasma volume and circulating plasma protein variations in disease are offered in Tables 5 and 6 — correlative to Tables 2 and 3, respectively.

We are constantly reminded that the patient was associated with animals, both sick and well. This suggests tularemia and brucellosis, which in this vicinity are more chronic in their course, without pronounced affection of the nervous system. Rabies runs a course even shorter than that in this case. The chief symptom — hydrophobia — is not mentioned, and the spinal fluid in such cases is normal. As for distemper, it is my understanding that this disease does not attack man.

Food poisoning, suggested by the fact that the patient and his family had mild attacks of diarrhea, indicates the possibility of botulism and other neurotropic poisons. It is my impression that none of these give abnormal spinal-fluid findings, nor is the gastrointestinal picture a dominant one. Myasthenia gravis may cause death from respiratory paralysis as may infectious poliomyelitis. But the clinical picture and course are so different from those in the case under discussion that they can hardly be considered.

A frequent cause of acute bulbar palsy is thrombosis of the basilar artery or its branches. In a patient of this age the usual etiologic factor, arteriosclerosis, should be absent. The presence of a septic embolus may be considered because of the cardiac murmur, but it is usual for emboli to pass up the internal carotid arteries rather than the vertebral vessels.

By process of exclusion, none of the above diagnoses fit this case. The onset, the clinical course, the symptomatology and the physical and spinal-fluid findings are typical of acute poliomyelitis of the bulbar type, which is my diagnosis. Incidentally, if this case had been reported twenty-five years ago, I should have included encephalitis lethargica as of equal likelihood to poliomyelitis — the findings in the bulbar types of that disease were in every way consistent with those in this patient. My diagnosis of acute poliomyelitis of the bulbar type is made with the reservation that my knowledge of animal diseases causing virus infections of the nervous system is limited.

DR AUGUSTUS S. ROSE: I should like to ask Dr Ayer to discuss the recurrence of the Babinski sign.

DR AYER: It sometimes happens in poliomyelitis that, although the gray matter is primarily involved, the white matter is also infiltrated and a transitory, not a permanent, Babinski sign is found. That was characteristic of the cases of encephalitis lethargica that simulated poliomyelitis. Also, one wonders if the Babinski sign was persistent, a single observation of a positive sign must be confirmed.

DR ROSE: I should also like to ask about the absence of a stiff neck in bulbar poliomyelitis.

DR AYER: That is not so frequent in this type as in poliomyelitis affecting the spinal cord.

There are two additional points that should be mentioned. In an epidemic in this vicinity some

years ago, Crone* analyzed a series of cases of bulbar poliomyelitis in which the reaction of the patients in the respirator was of great interest. They died not only in spite of the respirator but also, perhaps, because of it. It is interesting that in this case the intercostal muscles were spared.

The second point is that in these cases the higher the sugar in the spinal fluid, the worse the prognosis, that has never been explained to my knowledge. The sugar was elevated in this case. The temperature was high for the usual case of poliomyelitis. Why did you not ask about that? Patients with bulbar poliomyelitis often run high temperatures, whereas those with the ordinary type run temperatures of around 100 to 102°F — usually 101°F.

DR CHARLES S. KUBIK: You saw the patient Dr. Rose. Do you wish to add anything?

DR ROSE: We thought that this was a case of bulbar poliomyelitis. We considered the extensor plantar reflex on the one hand and the difficulty in the respirator on the other to have been due to bulbar involvement outside the anterior-horn cells — in other words, that encephalitis, as well as anterior poliomyelitis, was present.

DR AYER: The diagnosis may well include encephalitis, but the terminal picture was hardly enough to indicate encephalitis because anoxemia offers a sufficient explanation.

CLINICAL DIAGNOSIS

Anterior poliomyelitis, bulbar type

DR AYER'S DIAGNOSIS

Acute poliomyelitis, bulbar type

ANATOMICAL DIAGNOSIS

Poliomyelitis, bulbar type

PATHOLOGICAL DISCUSSION

DR KUBIK: This was a case of poliomyelitis. The temperature, which was high on admission, dropped and rose again. Because of the difficulty in swallowing, the question of aspiration pneumonia was raised. There was bronchopneumonia, but no definite aspiration pneumonia. As in most fatal cases of poliomyelitis there were lesions not only in the medulla and spinal cord but also in the pons, midbrain, basal ganglions and cerebral cortex.

The cortical lesions are usually not extensive, and so far as I know never give rise to focal signs, in my experience they are likely to be found in the anterior central convolutions. Another interesting feature is that there is usually good functional recovery of the paralyzed bulbar muscles in nonfatal cases of poliomyelitis and that there is, as a rule, comparatively little destruction of the nerve cells.

CASE 33011

PRESENTATION OF CASE

A thirty-five-year-old operator of a mink farm and dog kennel entered the hospital because of difficulty in swallowing.

Eight days before entry the patient, as well as the other members of his family, had had a mild bout of diarrhea, which had subsided completely in two days. Four days before entry he noticed a slight pain in the back and on the next day developed nausea and vomiting. In the evening the temperature rose to 100.5°F. Vomiting continued, the palate became sore and swollen, and the temperature rose to 102°F. On the day of admission the nausea abated, but difficulty in swallowing developed, so that mucus and saliva collected in the throat, causing great discomfort and difficulty in breathing. The patient gagged on liquids unless he was extremely careful. He regurgitated fluids through his nose and could not open his mouth as wide as usual. He had had no headaches, diplopia, pain, muscle tenderness or cough.

During the previous winter many of the patient's dogs had died from a virus infection identified at a state university as similar to but not identical with distemper.

Physical examination revealed a well nourished man whose respirations were shallow but not rapid. He was not cyanotic. The voice was thick and indistinct and had a nasal quality. The pharynx was injected. There was a Grade II, blowing systolic murmur heard best over the sternum slightly to the left of the midline in the third interspace. The lungs and abdomen were normal. Neurologic examination showed a questionable weakness of the left side of the face. The pharyngeal constrictors were weak. The neck muscles—particularly the right sternomastoid—were weak. The neck was not stiff. The arms and legs had good strength. There was no muscle tenderness. The tendon reflexes in the arms were not obtainable. The right knee jerk was questionably absent, the left knee jerk and both ankle jerks were present. There was an extensor plantar reflex on the right. Sensation was normal.

The temperature was 104.3°F, the pulse 80 and the respirations 28. The blood pressure was 140 systolic, 60 diastolic.

Examination of the blood disclosed a hemoglobin of 16 gm and a white-cell count of 12,000, with 72 per cent neutrophils. The urine was normal. The spinal fluid had an initial pressure equivalent to 200 mm of water. There were 26 lymphocytes and 2 polymorphonuclear leukocytes per cubic millimeter. The total protein was 70 mg, the sugar 86 mg and the chloride 667 mg per 100 cc. The gold-sol test was 0001232110.

Despite frequent suctioning of the pharynx the patient was unable to sleep because of the accumulating mucus. The respirations were good. On the second hospital day, the temperature dropped to 100°F, and he appeared somewhat improved. Nevertheless he was started on prophylactic penicillin at the rate of 24,000 units every three hours. During the night, he again had difficulty with mucus. On the third hospital day he was disoriented and picking at the bedclothes. Breathing was good, and the chest clear. The temperature rose to 101°F.

On the fourth hospital day the patient was unresponsive, cyanotic and bathed in perspiration. The lungs were clear, and the chest expanded well without the use of accessory muscles. The temperature now fell to 98°F. After the administration of oxygen by mask the cyanosis diminished and the pulse rate improved. The patient was then placed in a respirator. Breathing was gasping, irregular and asynchronous with the respirator. Mucus gathered rapidly. The pulse gradually became too weak to be felt. Finally, respirations ceased.

DIFFERENTIAL DIAGNOSIS

DR JAMES B AYER. We are evidently dealing with a rapidly progressive, acute, febrile disturbance affecting chiefly the brain stem, particularly the medulla. That a lesion or lesions were present in the medulla is indicated by the abnormal findings in the spinal fluid, which suggest either a virus infection or a reaction to local irritation. Although the lesion was dominant in the medulla and pons and undoubtedly caused the patient's death, there is some evidence that the spinal cord was also involved, as shown by the absent reflexes in the arms and the unequal reflexes in the legs. The terminal disorientation does not necessarily indicate implication of the cortex, the mental picture being readily explained on the basis of anoxemia.

In so-called "acute bulbar palsy" many diagnoses must be considered. All forms of acute bacterial meningitis are excluded by the absence of meningeal symptoms and by the type of spinal fluid.

Diphtheria is a possibility, but the lack of mention of a membrane in the throat and the abnormal spinal-fluid findings exclude this diagnosis.

time I do not know what the red macules on the chest were. They may have been important.

DR TRACY B. MALLORY: The dermatologist's opinion was that they were characteristic of bromide rash.

DR AUB: The scoliosis immediately makes one doubt the significance of any physical findings in the chest, because as soon as severe scoliosis is encountered, physical findings in the chest are altered by changes in aeration in the lung. The increased white-cell count and the red cells in the urine could have been due to hypernephroma involving the vena cava and obstructing the return blood flow from the other kidney, or to metastases to the other kidney.

The course suggests metastases not from the lung but from elsewhere, and one thinks, of course, of hypernephroma. The elevated temperature might have been due to either a primary infection or one caused by an occluding neoplasm. It does not establish an infection, however, because hypernephroma in itself causes fever. The pleuritic pain is also somewhat more suggestive of hypernephroma than of primary tumor of the lung, unless there was a good deal of infection, with subsequent irritation of the pleura, due to the primary tumor of the lung.

The patient was operated on on the eighth day. The type of procedure performed must be questioned. This was not the type of case that requires an extensive operation. If this man had been my patient, I should have handled him by doing a bronchoscopy, which is probably the operation that is referred to.

In these discussions I do not like to put in every possible diagnosis so as to be sure to include everything that was wrong with the patient. I think that it is better to list only likely diagnoses. There are three probable diagnoses in this case. One is primary infection of the lung that lasted four months and came and went, giving the recurrent symptoms, but that seems unlikely. Although the first bronchoscopy showed only chronic infection, a primary bronchiogenic neoplasm and metastases of a hypernephroma are the other two conditions that need serious thought. The diagnosis practically depends on the x-ray films. I do not believe that a proper differential diagnosis can be made without inspection of the films, but before that I should like to make one or two remarks. I think that this was probably a neoplasm, the most important thing is the location. If it was close to the hilar region, one must make the diagnosis of a primary, bronchiogenic neoplasm, with infection behind it caused by obstruction of the bronchus. If the neoplasm was out in the periphery it was probably metastatic hypernephroma. A duration of six years is not too long for metastases from a hypernephroma. I have seen cases in which these tumors were silent for thirteen years and then ran a virulent course, in spite of the fact that hypernephroma generally metastasizes early.

May we see the x-ray films?

DR LAURENCE L. ROBBINS: We have the good fortune of having the original films that were taken at the onset of the illness. They show the beginning of the lesion in the left upper lobe. Films taken while the patient was in the hospital show a considerable increase in the process. It first started as a rather nodular lesion, suggesting a multiplicity of nodules. By the time of admission there had been involvement of the lingular and lateral branches of the left upper lobe. There was some collapse, and the process was located in the anterior portion of the upper lobe. So far as could be determined at the original examination, the right upper-lung field was clear, and on the second examination it was essentially so, by the time the patient entered the hospital, however, there was evidence of something abnormal in the right upper lobe. I put up this film of the abdomen because it shows the scoliosis that was noted. There is a shadow in the region of the right kidney, which is not unusual, since after the kidney has been removed a shadow is frequently seen, suggesting that the kidney is still there — apparently, the area fills in with blood and the perirenal fat persists. I do not see the shadow of the psoas muscle, possibly because of the scoliosis.

DR DONALD S. KING: The dates of these films are interesting.

DR ROBBINS: This first film was taken in April, 1945, and the next series in March, 1946.

DR AUB: The indefinite lesion in the right apex was probably important, but I shall neglect it because I do not know what it is. The danger in not making a diagnosis of hypernephroma is that such a tumor often metastasizes to the lung, one should not make the mistake of neglecting it, saying that the lesion in the lung is a new one. It is probably unwise to do so, but I am going to do just that. The reason I do not believe that this was hypernephroma is that the position of the lesion was unusual for that diagnosis. The facts that sway me are that it was a single lesion, that it had been present for a year, that it started fairly near the hilus and extended along lines that look like the bronchi, and that the lung had collapsed peripheral to the tumor, suggesting that the lesion had occluded a bronchus rather than being out in the alveoli originally. I think that this man had infection in the collapsed upper lobe beyond the occluded bronchi. I have not forgotten, as I pointed out above, that patients with hypernephroma are likely to have fever without apparent infection. I think that this man had a primary bronchiogenic neoplasm, which may well not have been found at bronchoscopy because it was in a location difficult to see. As a matter of fact, I should not be surprised to hear that this had been caused by a metastasis from the hypernephroma — indeed, I consider it highly likely that it was. That is my second guess.

in the motor nuclei of the brain stem, even in severe and fatal cases with extensive microglial proliferation and perivascular infiltration in the same nuclei.

The anterior-horn cells of the spinal cord, for some reason, are particularly vulnerable. In another case all the anterior-horn cells on both sides were destroyed, whereas the cells of the columns of Clarke were intact. In the same case, in which death occurred five weeks after the onset, the cells had degenerated in a posterior root, presumably indicating degeneration of cells of a posterior spinal ganglion. Involvement of the ganglions or of the ganglions and posterior roots, probably explains the radicular type of pain that is often present in the early stages of the disease.

CASE 33012

PRESENTATION OF CASE

A forty-seven-year-old credit manager was admitted to the hospital with a history of cough.

Four months before admission, the patient had caught a "cold," following which a cough had persisted intermittently. He raised moderate amounts of foamy sputum with occasional flecks of bright-red blood. There were four febrile episodes, each lasting for about a week, during which the cough and sputum were accentuated. In the afternoons the temperature rose to 101 and occasionally to 103°F, with chilly sensations but no shaking chills. During this period the patient lost 15 pounds in weight. There had been a feeling of soreness and occasionally of pain in the left upper anterior portion of the chest that in the last three days before admission had become pleuritic. At the onset of the cough x-ray examination had revealed what was called a "tumor" in the left upper portion of the lung, and bronchoscopy had disclosed only inflammation, according to the patient. A month before admission another x-ray film revealed the same findings, and arrangements were made for admission to the hospital. For the next three weeks he complained of hoarseness and anorexia.

The patient had had poliomyelitis as an infant, with paralysis of the right leg and left foot and subsequent recovery except for considerable atrophy and some shortening of the right leg. He had had the usual childhood diseases, as well as typhoid fever at the age of ten. About ten years before entry, he complained of right midabdominal pain, and four years later a "hypernephroma" of the right kidney was removed. An x-ray examination of the lungs was made every three months until four years before admission, with negative findings, and the patient remained completely healthy until the onset of the present illness, except for occasional attacks of mild diarrhea.

Physical examination revealed a well developed and well nourished man. The trachea was slightly deviated to the left. There were some dullness to percussion over the left upper portion of the chest and marked diminution of breath sounds and tactile and vocal fremitus over the left upper anterior and posterior portions of the chest and apex. There appeared to be slightly less expansion of the chest on the left upper side than on the right. The voice was hoarse, and there were occasional red macules, 1 to 4 mm in diameter, on the chest. The right leg was about 2.5 cm shorter than the left. There was atrophy of the muscles of the right leg and of the left calf. There was a definite scoliosis of the spine to the right.

The temperature was 98.8°F, the pulse 92, and the blood pressure 130 systolic, 90 diastolic.

Examination of the blood disclosed a hemoglobin of 11.2 gm and a white-cell count of 23,200, with 82 per cent neutrophils, the red cells were moderately hypochromic. The urine had a specific gravity of 1.022 and gave a ++ test for albumin, with rare granular casts, 25 red cells and 2 white cells per high-power field in the sediment. The non-protein nitrogen was 27 mg, and the total protein 7.7 gm per 100 cc.

X-ray examination revealed an extensive haziness occupying the lower anterior portion of the left upper lobe, the interlobar septum was displaced forward. There was also a lobulated area of density extending upward into the midportion of the upper lobe. On the right side, there were areas of calcification in the hilus and there was haziness in the first interspace, more marked toward the axillary line. The dorsal spine showed curvature to the right, but the bones were otherwise not remarkable. A process in the right infraclavicular region had developed since previous films taken elsewhere. There was marked curvature of the upper lumbar spine, with convexity to the left and a spur formation of the right lateral margins of the vertebral bodies in this region. The skull, dorsolumbar spine and pelvis showed no evidence of metastases.

The patient developed a daily evening elevation of temperature to 102°F, with occasional pleuritic pains in the left upper portion of the chest anteriorly and a cough productive of thin, watery, mucoid sputum without blood. The chest signs remained unchanged. Penicillin had little effect on the fever. On the eighth day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. JOSEPH C. AUB: The past history suggests two diagnoses — primary tumor of the lung and metastasis from a so-called "hypernephroma" (renal-cell adenocarcinoma). Whatever the lesion was, it could have involved the recurrent laryngeal nerve. The patient had had symptoms for four years before the hypernephroma was removed. That is a long

FURTHER REASONS FOR THE NURSE SHORTAGE

A LETTER appearing elsewhere in this issue of the *Journal* was prompted by an editorial, "Shortage of Nurses," that was carried in the issue of September 12. The correspondent emphasizes that the life of the nurse in training is far from ideal, particularly as it pertains to recreational and social activities. Although it has long been an accepted idea that a nurse in training should lead a life in many respects comparable to that of a nun, there is little doubt that there is no need for such an attitude to persist in this present day and generation. That his statements in this regard are generally true is open to question, on the other hand, all training schools should make a careful study to determine whether

any change in the regulations governing the social life of their students is indicated.

The remarks concerning the traditional attitude of the surgeon in the operating-room also call for careful and thoughtful consideration. Picturesque as the old-time martinet master surgeon may have been, and interesting and amusing as it may be to read of the nurses and interns as they stood cowering about the operating table of the master and unable to make any defense against his attack, it is true that all these fireworks accomplished less than nothing regarding the care these subordinates gave in the particular case on the operating table. Nor did they prevent the reoccurrence of mistakes. It is surprising to observe the quick and eager response and the gratitude that result from a few quiet words of advice and a brief explanation of what the surgeon wants, furthermore, such conduct is extremely effective in attaining the desired result in the future. With service in the armed forces so recent to many, it is worth while recalling that one rule of the Army is excellent, even though it was not by any means universally applied. "Superiors are forbidden to injure those under their authority by tyrannical or capricious conduct or by abusive language."* This regulation recognizes the absolute necessity of treating subordinates in such a manner that their self-respect is preserved, and this attitude is equally applicable to civilian life.

There appears to be no single reason for the present shortage of nurses. It would be helpful, however, if hospitals, training schools and their professional staffs would do their part in making the life of a nurse more attractive than it is at present, thereby encouraging more young women of the proper type to enter the nursing profession.

DOCTORS EAST, DOCTORS WEST

DR EDWARD H. HUME,* under the title *Doctors East, Doctors West*, has recently published the account of his establishment of the Yale Hospital in Changsha in 1906, and the later founding of the Yale-in-China school of medicine. It is a book of intense interest to any doctor concerned with the

*Hume E. H. *Doctors East, Doctors West* 278 pp. New York W. W. Norton and Company Incorporated 1946

DR KING I should like to ask Dr Castleman whether it is true that a hypernephroma often metastasizes to the lumen of the bronchus

DR BENJAMIN CASTLEMAN It metastasizes somewhat in the manner of a sarcoma. It may metastasize to the bronchus and may produce spitting of blood. Dr King and I looked up this point some years ago.

DR MALLORY We have made a diagnosis of hypernephroma on bronchoscopic biopsy in at least one case — possibly more.

What procedure was performed, Dr King?

DR KING A lobectomy. We did not do another bronchoscopy. The patient had been bronchoscoped outside the hospital, and nothing had been found. Operation seemed indicated in any event.

CLINICAL DIAGNOSIS

Metastatic hypernephroma of left upper lobe of lung

DR AUB'S DIAGNOSIS

Primary bronchiogenic neoplasm, with collapse of lung alveoli and local infection

ANATOMICAL DIAGNOSIS

Metastatic renal-cell adenocarcinoma (hypernephroma) of left upper lobe of lung

PATHOLOGICAL DISCUSSION

DR MALLORY The specimen was an interesting one. We did find a metastatic renal-cell adenocarcinoma (hypernephroma). Almost the entire tumor lay within the bronchial tree, predominantly in the branches running toward the upper portion of the lobe. They appeared to be completely obstructed by plugs of tumor tissue, but the obstruction could not have been complete because the pulmonary tissue beyond the obstruction was not collapsed but was emphysematous. The alveoli were uniformly dilated, as they are in bronchial asthma or other conditions in which there is incomplete obstruction of the bronchus. There was an area of chronic pneumonitis of considerable size near the base of the lobe, but the bronchi leading to that area were not obstructed, so that although Dr Aub's logic is excellent, the specimen does not bear it out in any way.

DR AUB I should have discussed that because the x-ray films showed the neoplasm in areas where there was perfectly good aeration and did not indicate neoplasm in the areas where there was collapse.

DR KING We should probably have operated even if we had known it was hypernephroma, in the hope that we could rid the patient of metastases. There is the famous case of the patient who is living twelve years after the removal of such a pulmonary metastasis by Dr Churchill.^{1,2} That is one reason why we went ahead and tried to find x-ray evidence of metastases before operation — we could not find it.

Three weeks after operation the patient came in to the office with severe pain in the neck requiring morphine. In addition, he had a soft-tissue mass on the top of the head, x-ray examination showed a bony defect in the skull. He returned to the hospital, and gradually the pain went away. Later the mass on the top of the head disappeared. He had one convulsion and paralysis of the right leg, the paralysis also cleared. At present, several months after operation, the patient is better than he has been for a long time. I do not know what became of the soft-tissue mass in the scalp.

DR MALLORY Had any x-ray treatment been given, Dr Robbins?

DR ROBBINS Not so far as I know.

DR KING The patient was not given any, he had received some stilbestrol but only for a few days. It upset his stomach and was consequently discontinued.

DR ROBBINS This is the film taken prior to operation. I do not know whether you can see the definite defect in this portion of the parietal bone — it has disappeared since the original film. There was an area of approximately 2 cm. in length involving the outer table. The inner table is well preserved.

DR ALLEN G. BRAILEY What was the cause of the signs in the right apex?

DR KING More metastases, but we have not taken an x-ray film since then.

DR MALLORY The patient was placed on penicillin six days before operation, with quite a marked effect on the temperature chart. The day after operation the temperature dropped to normal. We still do not know whether the fever was due to pneumonitis or to the hypernephroma.

DR AUB Does hypernephroma cause fever without any other obvious cause?

DR MALLORY Unquestionably.

DR AUB This is another example of the fact that one should always pick out the obvious diagnosis.

program to include every Massachusetts resident as soon as possible

In order to ensure a fair distribution of the whole blood that is currently available, the following priority system has been set up *first priority* includes actual donors and members of their immediate families, *second priority* is given to residents of communities in which the Mobile Unit has taken blood, *third priority* goes to residents of communities in which the Mobile Unit is definitely scheduled to visit, and *fourth priority* takes in all other residents of Massachusetts. Emergency cases are given first consideration anytime that the required type of blood is on hand

SCHEDULE FOR MOBILE-UNIT VISITS

The Mobile Unit of the Massachusetts Blood Donor Program will make the following visits in the near future

COMMENT

Diseases reported at an incidence above the seven-year median included anterior poliomyelitis, diphtheria, German measles, malaria, Salmonella infections, typhoid fever and tuberculosis

Diseases reported at an incidence below the seven-year median included chicken pox, bacillary dysentery, measles, meningococcal meningitis, mumps, lobar pneumonia, scarlet fever and whooping cough

Diphtheria was reported at the highest prevalence for this month since 1933, being three times that of the corresponding month of last year

Poliomyelitis continued to occur much later than usual, resulting in a higher number of cases for the month than in 1945, although the total cases for the year to date is much lower

Lobar pneumonia continued to manifest the lowest incidence for this month, being less than one fourth that of the seven-year median. It again shattered the all-time record

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from Arlington, 1; Ashburnham, 8; Athol, 1; Boston, 5; Brookline, 2; Dover, 1; Easthampton, 3; East Bridgewater, 1; East Longmeadow, 1; Everett, 1; Falmouth, 1; Fall River, 1; Ipswich, 1; Lowell, 1; Lynn, 5; Milton, 1; Needham, 1; New Bedford, 1; Newton, 6; Orange, 1; Randolph, 1; Somerville, 1; Springfield, 1; Swampscott, 1; Upton, 1; Watertown, 1; Weston, 2; Worcester, 4; total, 55

Diphtheria was reported from Arlington, 1; Billerica, 1; Boston, 17; Brockton, 1; Cambridge, 2; Chelsea, 3; Dedham, 2; Easthampton, 1; Lowell, 3; Lynn, 1; Marlboro, 1; Medford, 2; New Bedford, 1; Newton, 1; Palmer, 1; Randolph, 3; Somerville, 14; Watertown, 2; Westboro, 2; Woburn, 1; Worcester, 1; total, 61

Dysentery, amebic, was reported from Murphy General Hospital, 1; total, 1

Dysentery, bacillary, was reported from Boston, 1; Worcester, 2; total, 3

Encephalitis, infectious, was reported from Haverhill, 1; North Adams, 1; total, 2

Malaria was reported from Amesbury, 1; Boston, 7; Leominster, 1; Montague, 1; Murphy General Hospital, 3; Springfield, 1; Worcester, 1; total, 15

Meningitis, meningococcal, was reported from Boston, 1; Lowell, 1; Montague, 1; New Bedford, 1; Worcester, 2; total, 6

Meningitis, Pfeiffer-bacillus, was reported from Billerica, 1; Cambridge, 1; Fall River, 1; Medway, 1; Salem, 1; total, 5

Meningitis, pneumococcal, was reported from Everett, 1; total, 1

Meningitis, other forms, was reported from Lowell, 1; total, 1

Meningitis, undetermined, was reported from Haverhill, 1; total, 1

Salmonella infections were reported from Boston, 1; Everett, 1; Haverhill, 4; Northfield, 2; Quincy, 1; Revere, 1; Salem, 3; Wellesley, 1; total, 14

Septic sore throat was reported from Amesbury, 8; Boston, 6; Merrimack, 7; Somerville, 1; total, 22

Trichinosis was reported from Bridgewater, 1; Malden, 1; Worcester, 2; total, 4

Typhoid fever was reported from Lowell, 1; Somerville, 1; Worcester, 1; total, 3

Undulant fever was reported from Gardner, 1; Northfield, 1; Quincy, 1; Southampton, 1; Worcester, 1; total, 5

CORRESPONDENCE

SHORTAGE OF NURSES

To the Editor: Reading the editorial "Shortage of Nurses" in the September 12 issue of the *Journal* was stimulus sufficient to make for finding and reading the editorial in the July 11 issue of the *Journal* and the editorial "The Training of the Graduate Nurse" in the July issue of the *Virginia Medical Monthly*

These articles take cognizance of the shortage of nurses, and in one it is suggested that the situation is a consequence of increasing educational requirements demanded for the registration of graduates. The seriousness of this state of affairs is apparent to all in the medical profession, and therefore needs no further comment

The motive for this letter came from the conviction that one obvious source of information had been neglected, that is the student nurse herself. Accordingly, I have, in the past few months, spoken to many nurses, attempting to unearth reasons why the profession is no longer so desirable as it once was

The major criticism was directed at the training itself. Graduates frequently said that if they had the choice to make again they would certainly not go into nursing training. A paradox was pointed out in that only girls whose high-school records indicated superior ability were accepted by the training schools of the better hospitals. Yet the demands on the trainees in these hospitals precluded learning to a large degree. Learning, it was thought, stopped almost entirely after the first year, for thereafter the hospitals seemed so bent on exacting the worth of the food and lodging supplied the trainee in actual work mass that a state of chronic fatigue

extension of his art and science, and to the student of Chinese ways and culture and history

It was only two years after the treaty opening Hunan Province to foreigners, and only five years after the memorable Boxer Rebellion, that Dr Hume entered what had been virtually a forbidden city, a year later he opened the Yeh Hospital, and waited for Yale's first patients in China. The story of the hospital's early days in the community and the place that it eventually found for itself, the starting of the medical school, the erection of new buildings, the Harkness gift and the eventual turning over of the Hsiangya Medical Educational Association to the provincial government make fascinating reading.

The substance of the book, however, is in the title, for its real story is of the meeting of Occidental with Oriental medical culture, and the lessons that each had to learn. According to a Chinese proverb,

**To read the medical classics exhaustively
Is not equal to frequent visits to the sick,**

and as some evidence of the value of this advice we find published about the year 196 A D. a treatise on typhoid fever by Chang Chungching, giving an accurate clinical description of the disease, with the advice to avoid violent purgatives in its treatment and to reduce the fever with cooling baths. Seaweed extracts for the treatment of certain kinds of goiter are recommended in classic Chinese medical literature, and fish-liver oils for tuberculosis, inoculation against smallpox was practiced from early times. One of the most interesting examples of Chinese medical perspicuity is found in the story of a Western woman treated unsuccessfully for pernicious anemia by Sir Patrick Manson in Amoy. Later a Chinese physician of the old school offered to cure her — and did — with large doses of crow's liver, decades before modern medical science had discovered the liver treatment of the disease!

Dr Hume tells of his consultation with Dr Wang, of the old school, and of their mutual arrival at the same diagnosis by different methods, for

**By nature men are nearly alike,
Their customs differ widely,**

and of his invitation to Dr Wang to give a course of lectures on the old art at the new medical school.

This was, indeed, the attitude that particularly fitted the author for his post, for

**He who looks back to the old
And knows the new
Is worthy to be a scholar**

MASSACHUSETTS MEDICAL SOCIETY BUREAU OF CLINICAL INFORMATION

All secretaries of various medical groups, such as special societies and alumni associations, are requested to notify the Bureau of Clinical Information regarding scheduled meetings, annual dinners and so forth. If such data are on file, it is hoped that duplication of dates can be avoided.

DEATHS

BERGERON — George G. Bergeron, M.D., of Ludlow, died September 26. He was in his fifty-sixth year. Dr. Bergeron received his degree from Temple University School of Medicine in 1917. He was a fellow of the American Medical Association.

SIMMONDS — Frederick J. Simmonds, M.D., of Jamaica Plain, died December 6. He was in his sixty-ninth year. Dr. Simmonds received his degree from Middlesex University School of Medicine in 1917. He was a fellow of the American Medical Association. His widow survives.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

PRIORITY SYSTEM ON FREE WHOLE BLOOD

When needed, whole blood may be obtained free by actual donors and members of their immediate families under a priority system now in effect for the Massachusetts Blood Donor Program. (Doctors and hospitals may continue to charge their usual fee for administration.)

Originally it was believed that the program could not undertake the distribution of whole blood until some time in 1947. The return of Army-Navy surplus stocks of plasma, however, enabled the Department of Public Health to supply Massachusetts hospitals with plasma from this reserve instead of using the blood from current donations for plasma production. This made it possible for the Department to turn its attention to processing fractions and developing the whole-blood phase of the program. In September, 1946, the Blood Donor Program began to furnish free whole blood for people who had actually donated to the program and for members of their immediate families. Although the distribution of whole blood has increased, there is still not enough to meet the need throughout the Commonwealth. The program is expanding steadily, however, and efforts are being made to extend the

PRESENTATION OF THE HENRY JACOB BIGELOW GOLD MEDAL

INTRODUCTORY REMARKS AND PRESENTATION OF THE MEDAL*

DONALD MUNRO, M D †

BOSTON

THE occasion of this meeting of the Boston Surgical Society is for the presentation of the Henry Jacob Bigelow Gold Medal. Tradition and custom, however, have decreed that some scientific contribution shall be made at every meeting of the Society. In consequence, the distinguished surgeon who will receive the Bigelow Medal, Dr. Frank H. Lahey, has been asked to present a paper. We are fortunate in that he has chosen thyroid surgery as his subject. He is well known to all in this audience and needs no further introduction. I have the honor of presenting Dr. Frank H. Lahey.

(Dr. Lahey then read a paper on thyroid surgery.)

The Boston Surgical Society was incorporated in November, 1914. In February of the following year, Dr. William Sturgis Bigelow presented the Society with the sum of five thousand dollars in memory of his father, Henry Jacob Bigelow, directing that the income derived from this sum of money be used from time to time for the presentation of a gold medal to be known as the Henry Jacob Bigelow Medal. The award is made for "new and valuable work in surgery or in fields connected with it." The medal was first awarded in 1921 to Dr. William J. Mayo. Since then eight other awards have been made, this present one being the tenth. The other recipients were Drs. William W. Keen, Rudolph Matas and Chevalier Jackson, Mr. George Grey Turner, and Drs. John M. T. Phinney, Harvey Cushing, Edward W. Archibald and Allen O. Whipple. Surgeons of the United States, England and Canada are represented.

The Society has been chary about awarding the medal to one of its own members, and it can be accepted as fact that before doing so it has interpreted the terms of the award with more than usual stringency. In consequence, only one member has previously received the medal. Dr. Harvey Cushing.

Tonight it gladly honors another member. Dr. Frank H. Lahey, director of the Lahey Clinic here in Boston, on the basis of his accomplishments not only in the field of surgery but also in those broader

fields that are connected with it well merits inclusion in this distinguished group of recipients. His mastery of thyroid surgery and surgery of the esophagus and bowel, for example, is but an indication of the scope of his technical skill. The presidencies of the American Medical Association and the New England Surgical Society, the governorship of the American College of Surgeons and membership, both honorary and regular, in many other surgical societies point to his great influence among the medical profession. He has held professorial posts in Harvard and Tufts College medical schools. The Lahey Clinic is famous for the opportunities it affords for graduate studies. Without his steadying influence during the war, the civilian physician situation would have been a serious menace to the public health. Even now, his influence is being continually exerted as a member of the Presidential Advisory Committee on the Integration of Medical Services in the Government to the end that, among other things, the veterans shall receive better care.

Nor should we forget in honoring Dr. Lahey to do equal honor to Mrs. Lahey. All in this audience know what profound influence a surgeon's wife exerts on the surgeon. Without her sustaining aid his courage would many times falter, without her encouragement he would never be inspired to rise to heights believed by him to be beyond his reach. She puts up with long lonely hours, a frequently disrupted household and those temperamental peculiarities that are characteristic of a person who by nature and by training is above all things an individualist. Dr. Lahey will, I am sure, agree with me that without the devoted and loyal support given him by Mrs. Lahey he would never have achieved even a modicum of the deserved success that has been his.

Dr. Lahey—superlative surgeon, doctor who teaches doctors, redoubtable administrator, adviser of Presidents in war and peace and, above all, a man who has the courage to be honest with himself—as the representative of the Boston Surgical Society I take great personal pleasure in having the honor to present to you in its name the Henry Jacob Bigelow Gold Medal.

*This and the succeeding paper comprise the addresses delivered at the presentation of the Henry Jacob Bigelow Gold Medal at a meeting of the Boston Surgical Society, Boston, May 10, 1946.

†President, Boston Surgical Society.

supervened. This prohibited intelligent reading, attention at lectures vacillated. Regarding duties, a tendency toward automatism became increasingly great and interest waned in why a patient with a given disease received a particular kind of therapy. Initiative succumbed as the consciousness of not learning became engulfed in a despair at being able to learn.

The attitudes of physicians toward students were often thought to be not that of gentlemen. Cursing, harsh words, incessant satire all were mentioned, frequently with rancor. Few doctors ever troubled to explain what was being done or why it was being done — as in the operating room, where the student worked for weeks watching operations designed to accomplish she knew not what, on patients she knew nothing of.

The social restrictions of a trainee's life weighted heavily with every nurse consulted. It seemed not at all clear to them as trainees, why they should lead cloistered lives. They are allowed liberty until midnight on five nights each month, whereas girls of comparable age in colleges or in their homes are considered mature enough to decide how often and how long social activities should be indulged in. An incongruity is manifest when this attitude is referred to a nurse's responsibilities with a seriously ill patient.

Finally, it was pointed out that following graduation, a registered nurse could expect a job working for more than eight hours at various times during the twenty-four hours of the day. Exposure to all the ills of mankind would be her lot, and for this she would receive less money than many secretaries — special duty nurses, it was admitted, do far well financially.

These thoughts were garnered in talking with nurses at the various hospitals to which students in the Harvard Medical School are assigned. I think that they certainly are valid and active reasons why there is a shortage of nurses. An examination of training-school statistics will reveal that some classes lose as many as 50 per cent of their original enrollment — admittedly, not all losses are due to the defects in the character of the training as described.

Succinctly, it is fair to say that from the point of view of the nurse, the shortage of nurses could in large measure be repaired by making the life of a student nurse more attractive — that is, by devoting more of the required three years to teaching and less of it to drudgery, by a real effort on the part of hospital staffs to improve attitude and conduct toward trainees, by attributing to student nurses a degree of maturity enjoyed by comparable groups of young women and by providing more nearly adequate recompense for graduates.

BOOK REVIEW

A Bibliography of Infantile Paralysis, 1789-1944. With selected abstracts and annotations. Prepared under the direction of The National Foundation for Infantile Paralysis, Incorporated. Edited by Morris Fishbein, M.D. Compiled by Ludvig Hektoen, M.D. 4th ed., cloth, 672 pp. Philadelphia: J. B. Lippincott Company, 1946.

A bibliography of infantile paralysis has long been needed by the medical profession, librarians, public-health officials and the public at large. The subject has grown to vast proportions, and Dr. Ludvig Hektoen and his associates, under the general editorship of Dr. Morris Fishbein, have compiled and annotated over eight thousand selected references for the National Foundation for Infantile Paralysis. The book is more than a list of papers, for the most important references have been carefully evaluated and a brief summary, usually less than six lines in length, gives the essential material contained in the article, sometimes disclosing facts that are not implied in the title of the paper. It is this aspect of the bibliography that makes the book of particular importance to the medical profession.

Beginning with the paper by Underwood in 1789, the bibliography continues through the year 1944. There are a full index of authors and a subject index giving references to the many aspects of poliomyelitis that have been investigated in the past. Thus, one can readily find out the most significant references to such subjects as facial-nerve paralysis in poliomyelitis, flies as carriers of the disease, seasonal in-

cidence, the cerebellar form of poliomyelitis, the involvement of the cerebrospinal fluid, chronic anterior poliomyelitis, quarantine, Theiler's virus and the relation of tonsillectomy to poliomyelitis.

The book is a good example of co-operative research by a chief editor and a fully qualified medical reference librarian. It can be recommended without question as a standard work. The volume is singularly free from error, usually complete and clearly printed, with two indexes that are among the best that have ever been assembled. The editor and the compiler are to be congratulated on the publication of an outstanding work on infantile paralysis.

NOTICES

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY

The next written examination and review of case histories (Part I) for all candidates will be held in various cities of the United States and Canada on Friday, February 7, 1947.

Arrangements will be made, so far as is possible, for candidates to take the Part I examination (written paper and submission of case records) at places convenient for them. Candidates who successfully complete the Part I examination proceed automatically to the Part II examination to be held June 1-7, 1947, at Pittsburgh. Notice of the exact time and place of the Part I and Part II examinations will be sent to all candidates well in advance of the examination date.

For further information and application blanks address Paul Titus, M.D., Secretary, 1015 Highland Building, Pittsburgh 6, Pennsylvania.

PUBLIC-HEALTH FELLOWSHIPS FOR PHYSICIANS AND ENGINEERS

Announcement is made by Surgeon General Thomas Parrish of the United States Public Health Service that applications for fellowships in postgraduate public-health training for physicians and engineers for the school year beginning in the fall of 1947 will be received at any time prior to May 1, 1947.

The fellowships are made possible by a grant of \$228,400 from the National Foundation for Infantile Paralysis through funds contributed to its "March of Dimes." Fifty-three students were awarded fellowships for the school year beginning in September, 1946.

The fellowships provide graduate training of approximately nine months in an accredited school of public health or an acceptable school of sanitary engineering, followed by three months of field training, and are open to men and women, citizens of the United States, under forty-five years of age. Physician applicants must have completed at least a year's internship. Engineering graduates with a Bachelor's or higher degree in sanitary, civil or chemical engineering are eligible, and those with other engineering degrees who have had experience in the public-health or sanitary engineering field may also submit applications.

The specific purpose of the fellowships is to aid in the recruitment of trained health officers, directors of special services and engineers to help fill hundreds of vacancies existing in state and local health departments throughout the country. The fellowships are intended for newcomers to the public health field and are not open to employees of state and local health departments, for whom federal grant-in-aid funds are already available to the states.

Applicants for fellowships may secure further details by writing to the Surgeon General, United States Public Health Service, 19th and Constitution Avenue, N. W., Washington 25, D. C., Attention: Public Health Training.

uch we are greatly indebted to Dr E B Astwood, no longer need surgeons fear even the seriously toxic patients with hyperthyroidism in whom, in the first, multiple-stage procedures were frequently necessary.

Because thiouracil, thiobarbital and propylthiouracil so positively and dependably bring the metabolic rate to normal in patients seriously affected by hyperthyroidism because these danger-

quickly than several men, acquires familiarity with the advantages and dangers related to the administration of this useful drug in preparing patients with hyperthyroidism for surgery.

In an article on this subject published by the Clinic,¹ a simple diagram (Fig 2) was employed to illustrate the origin of hyperthyroidism, together with what has been suggested by many as the possible way in which these drugs bring about a

FIGURE 1 Photographs of Patient with Severe Hyperthyroidism before and after Operation. The photograph on the left shows the extreme degree of emaciation that can result when the disease is untreated, that on the right shows the normal state that was attained after subtotal thyroidectomy.

ous but useful drugs will abolish multiple-stage procedures in the surgery of hyperthyroidism, because they will still further reduce, if not abolish the already low mortality, — a patient mortality of 0.88 and an operative mortality of 0.73 per cent, as compared with a patient mortality of 0.17 per cent with the use of these agents, — and because we have now employed these drugs in preparing for surgery over 500 patients with hyperthyroidism, it is important to report our experience with them. Because these powerful controllers of thyroid hyperactivity have real dangers, as well as real advantages, some of their complications are discussed.

Desiring to concentrate experience with these dangerous drugs in the hands of one man so that he could have the largest possible experience with them, we have turned over their administration in the preparation of patients with hyperthyroidism for surgery at the Clinic to Dr Elmer C Bartels. By this plan, which I recommend for any hospital using this dangerous drug in the treatment of patients with hyperthyroidism, one man, much more

return of the elevated basal metabolic rate to normal and thus abolish the symptoms of hyperthyroidism associated with the elevated metabolic rate.

Early in our experience in operating on patients with hyperthyroidism who had had their metabolic rates brought to normal by these drugs, we became distressingly aware of the fact that, although the patients were freed from toxicity, the thyroid glands themselves were in the same state as those before the introduction of Lugol's solution by Dr Henry S Plummer to prepare the patients for surgery. The thyroid glands of patients prepared with thiouracil alone were friable and vascular and did not hold double hooks, ligatures cut through, bleeding was almost uncontrollable, and microscopic section — in spite of the fact that these patients were free from toxicity — showed the glands still to be markedly hyperplastic, including all the features found in patients with severe hyperthyroidism untreated with iodine.

As may be seen in Figure 2, the effect of thiouracil, as has been suggested by many, is an extrathyroid

SURGERY OF THE THYROID GLAND*

FRANK H LAHEY, M D †

BOSTON

I HAVE selected the subject "Surgery of the Thyroid Gland" because the Lahey Clinic and I have literally grown up almost from the beginning of the developments in this field and have had a hand in bringing about some of them, because this experience represents almost as large an acquaintance with the subject as exists in the world today and has therefore made available to us a considerable knowledge of the unusual thyroid states with which men not dealing with these conditions daily are often not familiar, because it is particularly appropriate to present a review of this special experience in the community in which it has been had and to a group of surgeons with whom I have lived and who have been my friends and colleagues and, finally, because in the audience to which it is presented are many of my lay friends who I hope will be able to understand and be interested in at least more of the aspects of this review than would be true of a perhaps more erudite but less dramatic subject.

Since this presentation is in the nature of a review and a report on this experience, the material represents the work of many men in the Clinic, much of which has been published in special papers on the various individual aspects of thyroid disease. Because the subject lends itself so well to illustrative demonstration, each aspect is demonstrated, so far as possible, by illustrations, making it, I hope, additionally comprehensible to the nonprofessional portion of the audience.

This review is based on an operative experience with between 25,000 and 26,000 thyroid operations on between 22,000 and 23,000 patients with thyroid disease (Tables 1 and 2). Since this paper deals

absence of the thyroid gland and other nonsurgical thyroid states.

The developments in this disease are discussed not only from the standpoint of better management in its various aspects but also to demonstrate progress in the attempt to educate the family physician, who first sees these patients, to deal with them more aggressively and at an earlier stage, before they have reached advanced degrees of emaciation and intoxication.

I have purposely selected two old photographs (Fig 1) to demonstrate the state of intoxication to which these patients with hyperthyroidism were in the past often permitted to go, and, in the same patient, the result following subtotal thyroidectomy. This is also a graphic demonstration of what hyperthyroidism actually is. Hyperthyroidism, as can be

TABLE 2 Mortality following Thyroidectomy

Number of operations	25,000
Operative mortality	0.75%
Number of patients	22,000
Patient mortality	
All cases	0.83%
Cases since July 1, 1943	0.37%
Cases during 1945	0.17%

seen from these two illustrations preoperatively and postoperatively, is a disease brought about by hypermetabolic activity, stimulated, in turn, by the excessive synthesis of thyroxine. It is now well known that the excessive synthesis of thyroxine causes the weight loss dramatically illustrated in Figure 1, which is only the external evidence of the unseen but real effects of excessive metabolism on inner, nonvisible structures, such as the liver, the heart, the epiphyseal centers in young children, the intestinal tract and the retro-ocular muscles and fat, that play a large part in intractable exophthalmos (see Figs 7, 8, 12, 17, 18 and 19).

The introduction of iodine in the preparation of patients for subtotal thyroidectomy for hyperthyroidism, together with the improvement in technical procedures and in anesthesia and the better preoperative preparation and postoperative care of these patients, has resulted in such a lowering of mortality rates that the family physician no longer delays recommending operation until the patients have reached the states shown in Figure 1.

Thiouracil, Thiobarbital and Propylthiouracil

As the result of the development of the use of thiouracil, thiobarbital and propylthiouracil, for

TABLE 1 Types of Thyroid Disease

Disease	No. of Cases
Hyperthyroidism including primary hyperthyroidism and adenomatous goiter with secondary hyperthyroidism	16,000
Nontoxic goiter	9,000
Total	25,000

particularly with the surgical treatment of thyroid disease, no mention is made of other states that rarely require surgery, such as diffuse colloid goiter, endemic and nonendemic, thyroiditis of the Riedel's struma type and of the Hashimoto's struma lymphomatosa type, lingual goiter, sublingual goiter, thyroid tuberculosis, syphilis and abscess, unilateral

which we are greatly indebted to Dr E B Astwood, no longer need surgeons fear even the seriously toxic patients with hyperthyroidism in whom, in the first, multiple-stage procedures were frequently necessary.

Because thiouracil, thiobarbital and propylthiouracil so positively and dependably bring the metabolic rate to normal in patients seriously affected by hyperthyroidism, because these danger-

ously than several men, acquires familiarity with the advantages and dangers related to the administration of this useful drug in preparing patients with hyperthyroidism for surgery.

In an article on this subject published by the Clinic,¹ a simple diagram (Fig 2) was employed to illustrate the origin of hyperthyroidism, together with what has been suggested by many as the possible way in which these drugs bring about a

FIGURE 1 Photographs of Patient with Severe Hyperthyroidism before and after Operation. The photograph on the left shows the extreme degree of emaciation that can result when the disease is untreated, that on the right shows the normal state that was attained after subtotal thyroidectomy.

ous but useful drugs will abolish multiple-stage procedures in the surgery of hyperthyroidism, because they will still further reduce, if not abolish the already low mortality, — a patient mortality of 0.88 and an operative mortality of 0.73 per cent, as compared with a patient mortality of 0.17 per cent with the use of these agents, — and because we have now employed these drugs in preparing for surgery over 500 patients with hyperthyroidism, it is important to report our experience with them. Because these powerful controllers of thyroid hyperactivity have real dangers, as well as real advantages, some of their complications are discussed.

Desiring to concentrate experience with these dangerous drugs in the hands of one man so that he could have the largest possible experience with them, we have turned over their administration in the preparation of patients with hyperthyroidism for surgery at the Clinic to Dr Elmer C Bartels. By this plan, which I recommend for any hospital using this dangerous drug in the treatment of patients with hyperthyroidism, one man, much more

return of the elevated basal metabolic rate to normal and thus abolish the symptoms of hyperthyroidism associated with the elevated metabolic rate.

Early in our experience in operating on patients with hyperthyroidism who had had their metabolic rates brought to normal by these drugs, we became distressingly aware of the fact that, although the patients were freed from toxicity, the thyroid glands themselves were in the same state as those before the introduction of Lugol's solution by Dr Henry S Plummer to prepare the patients for surgery. The thyroid glands of patients prepared with thiouracil alone were friable and vascular and did not hold double hooks, ligatures cut through, bleeding was almost uncontrollable, and microscopic section — in spite of the fact that these patients were free from toxicity — showed the glands still to be markedly hyperplastic, including all the features found in patients with severe hyperthyroidism untreated with iodine.

As may be seen in Figure 2, the effect of thiouracil, as has been suggested by many, is an extrathyroid

one, possibly on inorganic iodine, which the thyroid gland synthesizes into organic iodine, either by so affecting the iodine that it is no longer satisfactory for synthesis or by its effect on the proteolytic action of the gland so that organic iodine (thyroxine) is no longer synthesized.

If iodine is no longer synthesized into thyroxine, one can understand what Bartels² has observed in patients with hyperthyroidism to whom one of these three drugs had been administered with reasonable regularity one can assume that, to bring the metabolic rate to normal, a full dosage of these drugs (0.6 gm of thiouracil, 50 mg of thiobarbital or from 175 to 225 mg of propylthiouracil) will take approximately the number of days that the metabolic rate has been above normal. This finding

tion brought about in the patient shown in Figure 1 by the administration of Lugol's solution and demonstrates the dilatation of the acini and the compression of the epithelial cells lining the acini. This is called "involution effect" brings about devascularization, firmness and almost ideal operating conditions.

FIGURE 2 Physiologic Changes in Primary Hyperthyroidism following Thiouracil Therapy

Thiouracil brings about the return of the basal metabolic rate to normal and abolishes the symptoms of hyperthyroidism without changing the histologic picture of hyperthyroidism within the gland and without inhibiting the pituitary-stimulating hormone, which incites the hyperplasia within the thyroid (reproduced from Lahey et al¹ by permission of the publisher)

is predicated on the reasonable basis that this period represents the time necessary to use up the thyroxine already manufactured and stored in the tissues and in the thyroid gland, it has been demonstrated that these drugs have no effect on the efficacy of thyroxine already manufactured and that their effect is only in preventing the synthesis of more thyroxine.

Figure 3 shows a high-power photomicrograph of the friable, high-columnar epithelial cells lining the acini in the hyperplasia associated with the overactive thyroid gland of hyperthyroidism untreated with iodine. This type of hyperplasia is seen in patients with hyperthyroidism whose metabolic rate has been brought to normal with thiouracil, thiobarbital or propylthiouracil and in whom, because of this persisting hyperplasia, operating conditions are unsatisfactory. Figure 4 illustrates the involu-

FIGURE 3 High-Power Photomicrograph of the Columnar Epithelial Cells Lining the Acini

This is the histologic picture found in the patient with hyperthyroidism whose metabolic rate has been brought to normal with thiouracil; it demonstrates why the thiouracil-prepared thyroid gland bleeds so excessively.

in patients prepared for surgery with Lugol's solution.

Because of the undesirable operating conditions in patients with hyperthyroidism prepared solely with thiouracil, thiobarbital or propylthiouracil, Dr. Bartels and I have devised a plan combining the advantages of thiouracil and iodine. Figure 1 demonstrates the typical course, with a drop in the basal metabolic rate and a gain in weight, in a patient with hyperthyroidism during the period in which thiouracil was administered and in the final three-week period during which iodine was administered, the desirable effects of both drugs being obtained. By this means it is possible to prepare patients with severe hyperthyroidism for surgery so that ideal operating conditions are established. The metabolic rate is brought to normal, the symptoms of hyperthyroidism disappear and the gland is converted into an avascular, firmly involuted one that can be managed technically with complete satisfaction.

Table 2 presents the patient and the operative mortality in our entire series of thyroid operations,

arting with the period from our very first case and cluding the period when we had had relatively the experience with the disease, as well as the

FIGURE 4 Low-Power Photomicrograph of Thyroid Gland This demonstrates involution brought about by the intrathyroid effect of iodine and shows the dilatation of the acini, the compression of the epithelial cells lining the acini and the production of firmness and devascularization, which furnish ideal operating conditions

period before iodine was used in the preparation of the patients. The patient mortality for the entire series was reduced from 0.88 per cent on July 1,

patient who died of coronary disease. During this period no multiple-stage operations were performed. The average stay in the hospital has decreased from fifty-five days in patients prepared with iodine who required three-stage operations and thirty-five days in patients prepared with iodine who required two-stage operations to eight days in patients prepared with one of these three drugs.

In 100 patients with severe hyperthyroidism treated with one of these three drugs, Bartels² has shown that the average basal metabolic rate was +49 per cent before treatment and +7 per cent after treatment and that the average weight loss before treatment was 25 pounds and the average weight gain after treatment, 12 pounds.

Complications occurring with the administration of these drugs can be — and have been — of a serious character. They consist of various degrees of neutropenia and granulocytopenia, fever, skin eruptions and enlargement of the salivary glands. Dr. Bartels has demonstrated that these complications can be anticipated in 9 per cent of patients treated with thiouracil and in 28 per cent of patients treated with thiobarbital. We have now operated on 60 patients prepared with propylthiouracil, with 100 others in preparation for surgery. Propylthiouracil has not as yet been employed long enough and in large enough doses to be certain of its complications. Two patients have already shown marked depressions of the white-cell count, in 1, the white-cell count was reduced to 1900, with no neutrophils. We strongly suspect that although propylthiouracil may produce fewer complications than the other

FIGURE 5 A Plan for the Preoperative Preparation of Patients with Hyperthyroidism by the Combined Use of Thiouracil, Thiobarbital or Propylthiouracil and Iodine It should be noted that Lugol's solution is given during the last three weeks of preparation, bringing about involution and ideal operating conditions. No thiouracil is given for the last week before operation because of the fact that agranulocytosis has occasionally been found to occur as late as seven days after the last dose of such drugs, a complication that would be undesirable either at the time of operation or during postoperative recovery (reproduced from Bartels² by permission of the publisher)

1943, when thiouracil was first used in the Clinic, to 0.27 per cent, and the patient mortality for the year 1945 was but 0.17 per cent, representing a

two drugs, it will prove capable of causing death if given in doses adequate to reduce the metabolic rate to normal (equivalent to 0.6 gm of thiouracil)

one, possibly on inorganic iodine, which the thyroid gland synthesizes into organic iodine, either by so affecting the iodine that it is no longer satisfactory for synthesis or by its effect on the proteolytic action of the gland so that organic iodine (thyroxine) is no longer synthesized.

If iodine is no longer synthesized into thyroxine, one can understand what Bartels² has observed in patients with hyperthyroidism to whom one of these three drugs had been administered with reasonable regularity one can assume that to bring the metabolic rate to normal, a full dosage of these drugs (0.6 gm of thiouracil, 50 mg of thiobarbital or from 175 to 225 mg of propylthiouracil) will take approximately the number of days that the metabolic rate has been above normal. This finding

tion brought about in the patient shown in Figure 3 by the administration of Lugol's solution and demonstrates the dilatation of the acini and the compression of the epithelial cells lining the acini. This so-called "involution effect" brings about devascularization, firmness and almost ideal operating conditions.

FIGURE 2 Physiologic Changes in Primary Hyperthyroidism following Thiouracil Therapy

Thiouracil brings about the return of the basal metabolic rate to normal and abolishes the symptoms of hyperthyroidism without changing the histologic picture of hyperthyroidism within the gland and without inhibiting the pituitary-stimulating hormone, which incites the hyperplasia within the thyroid (reproduced from Lahey et al.³ by permission of the publisher)

is predicated on the reasonable basis that this period represents the time necessary to use up the thyroxine already manufactured and stored in the tissues and in the thyroid gland, it has been demonstrated that these drugs have no effect on the efficacy of thyroxine already manufactured and that their effect is only in preventing the synthesis of more thyroxine.

Figure 3 shows a high-power photomicrograph of the friable, high-columnar epithelial cells lining the acini in the hyperplasia associated with the overactive thyroid gland of hyperthyroidism untreated with iodine. This type of hyperplasia is seen in patients with hyperthyroidism whose metabolic rate has been brought to normal with thiouracil, thiobarbital or propylthiouracil and in whom, because of this persisting hyperplasia, operating conditions are unsatisfactory. Figure 4 illustrates the involu-

in patients prepared for surgery with Lugol's solution.

Because of the undesirable operating conditions in patients with hyperthyroidism prepared solely with thiouracil, thiobarbital or propylthiouracil, Dr. Bartels and I have devised a plan combining the advantages of thiouracil and iodine. Figure 3 demonstrates the typical course, with a drop in the basal metabolic rate and a gain in weight, in a patient with hyperthyroidism during the period in which thiouracil was administered and in the final three-week period during which iodine was administered, the desirable effects of both drugs being obtained. By this means it is possible to prepare patients with severe hyperthyroidism for surgery so that ideal operating conditions are established. The metabolic rate is brought to normal, the symptoms of hyperthyroidism disappear and the gland is converted into an avascular, firmly involuted one that can be managed technically with complete satisfaction.

Table 2 presents the patient and the operative mortality in our entire series of thyroid operations;

Apathetic Hyperthyroidism

Because a chronic type of hyperthyroidism of low grade that frequently occurs in older people, to which I gave the name "apathetic hyperthyroidism" some years ago, is often overlooked, being different from the typical activated hyperthyroidism shown in Figure 6, I call attention to the existence of this atypical type, illustrated in Figure 7

I gave the name apathetic hyperthyroidism to this condition, not with any idea that it represented any special group but merely to call attention to the fact that there is a type of hyperthyroidism without eye signs, without activation, without marked enlargement of the gland and with only moderate tachycardia but particularly associated with marked weight loss and marked myasthenia over a long period and that because of the lack of these outstanding signs this type of hyperthyroidism is often overlooked. I also called attention to the fact several years ago that this type of hyperthyroidism, which is frequently associated with only moderate elevations in basal metabolic rates, is often approached too confidently by the surgeon because it does not have striking signs of overactivation, the condition is not given the attention and caution warranted by the reactions and fatalities that can occur following surgery in this type of hyperthyroidism.

I am sure, as I have repeatedly written, that there are many patients with such a low grade of this type of chronic hyperthyroidism, exhibiting such unstriking evidences of disease, who are undiagnosed in many communities. It is in these patients that proper preoperative preparation and subtotal thyroidectomy can achieve some of the most brilliant results in the surgery of hyperthyroidism.

Thyrocardiac Disease

Figure 8 shows a preoperative and postoperative view of a patient belonging in the group of thyroid conditions to which Hamilton and I³ gave the name thyrocardiac. It was with Dr. Hamilton's aid and

thyroidism⁴. It will be noted in this diagram, devised by Dr. Hurxthal, that in the patients with any limited cardiac capacity, the superimposed needs of increased circulation rate associated with an increased metabolic rate cannot be met by a compensatory increase of the circulation rate with an inadequately capable heart, the section illustrating the high metabolic rate with only a normal uncompensating circulation rate demonstrates why failure occurs and how it is possible, by means of subtotal thyroidectomy, which brings the metabolic

FIGURE 8 Photographs of a Thyrocardiac Patient before and after Subtotal Thyroidectomy

encouragement that I began our early surgical treatment of patients with cardiac failure, brought about by an associated hyperthyroidism.

Figure 9 graphically demonstrates why cardiac decompensation occurs in patients with hyper-

rate to normal, or by means of the administration of thiouracil, thiobarbital or propylthiouracil, which brings the metabolism to normal, to bring the circulation rate and metabolic rate into balance, with restoration of compensation. Figure 10 shows the cardiac shadow in a thyrocardiac with failure and the return of the cardiac shadow to normal following the elimination of the hyperthyroidism by subtotal thyroidectomy as graphic evidence of this accomplishment.

Table 3 presents the number of patients, of a total of 306 known to be living, who have obtained Grade I, Grade II and Grade III results among those who have been followed postoperatively for varying periods from 1922 to 1941. Grade I repre-

Dr Bartels has demonstrated that if these complications occur and the drugs are stopped and again administered, there will be an increased hazard of recurrence. He has also shown that agranulocytosis and neutropenia can occur up to seven or eight days after withdrawing the drug and as late as the ninth month after beginning treatment and on a dose as low as 0.2 gm of thiouracil. It is for these reasons that no thiouracil, thiobarbital or propylthiouracil is given for a week before the patient comes to operation (Fig 5), to avoid the coincidental occurrence of one of these states with the operative procedure or postoperative recovery.

When agranulocytosis and neutropenia — the most dangerous of all these complications — have occurred, no treatment can compare in usefulness with that of penicillin in large doses. Pyridoxine, vitamin B-6 and liver extract are administered together with penicillin, but penicillin is the single measure on which the greatest dependence can be placed.

These patients are kept under close observation, with frequent white-cell and differential counts, and

not be definitely answered at present. It can be answered only after a larger experience over a longer period. At present, it is Dr Bartels's experience that in patients with small thyroid glands who have had the disease for a short time, remissions may be accomplished. How long they will last, no one as yet

FIGURE 6 *Typical Activated Hyperthyroidism*
This should be compared with Figure 7, which shows typical apathetic hyperthyroidism

FIGURE 7 *Typical Apathetic Hyperthyroidism*
Note the lack of activation and thyroid enlargement and the wrinkled and pigmented skin

knows. In patients who have had the disease a long time and with large glands, recurrences will follow the withdrawal of the drug in a large percentage of cases.

Of these three drugs it appears reasonable to say that, at least so far, propylthiouracil appears to possess less danger of the complications that occur with thiouracil and thiobarbital, but is not free from danger, that these drugs, particularly thiouracil and thiobarbital, unless administered by one familiar with their use, will produce mortality rates as high as, if not higher than, that following expert surgery. In experienced hands, however, they will eliminate multiple-stage procedures and largely abolish the mortality of subtotal thyroidectomy. They will find their greatest usefulness in patients with hyperthyroidism with complicating states, such as diabetes, pregnancy and cardiac decompensation.

on the appearance of any real depression of either the white cells or the granulocytes, the drug is immediately withdrawn.

The final question regarding the employment of these three drugs is, Will it be possible by the use of one of them to eliminate the necessity for operation? Can the metabolism be maintained at a normal level over a long period, so that a persisting remission can be accomplished? This question can-

Apathetic Hyperthyroidism

muscles and the retro-orbital fat, resulting in edema-ous enlargement of the muscles and infiltration of the retro-ocular fat and thus crowding the eye forward and producing lid pressure on the conjunctiva, with consequent loss of nutrition and with ulceration and infection (Fig 13)

Up to ten years ago, we had seen eyes lost in 6 cases as the result of this condition. Since the employment of the Naffziger operation by the neurosurgeons of the Clinic, Drs Gilbert Horrax and James L. Poppen, no eyes have been lost in patients with intractable exophthalmos.⁶ Because

the periosteum of the orbit. There is a bulging of the retro-orbital fat as soon as the periosteal covering over the orbital canal is opened. Figure 16 illustrates diagrammatically the anatomy of the orbital canal, the segment of orbital plate to be removed, the bulging of ocular muscles and retro-orbital fat through the decompressed, unroofed, orbital cavity and the projection of the eye pre-operatively and its recession following decompression.

Although this operation, devised by Naffziger, will not abolish in many of the cases the unsightly

FIGURE 16 Diagrams Representing the Various Steps in Decompression of the Eyeball in Intractable Exophthalmos

of the serious danger to the eyes in patients with extreme exophthalmos I wish particularly to urge that, should there be any evidences of lid pressure, as shown in Figure 14, which illustrates the pre-operative state and postoperative result in such a case, prompt measures should be undertaken by means of orbital decompression to relieve this pressure. Figure 15 demonstrates the method of decompressing the orbital canal. After exposure, the parietal bone flap is turned down, the frontal lobe of the brain is turned up, the bony roof of the orbit is rongeuired away and an incision is made in

exophthalmos, it will, if done in time, prevent ulceration, infection and, if loss of blood supply has not already taken place, save the eye. It will obviously be of no value, however, to patients who are sent for management at the stage shown in the left eye in Figure 13.

Liver Function

In addition to the external results of the advanced stage of hyperthyroidism shown in Figure 1, serious nonvisible and often unappreciated effects are going

a patient with hyperthyroidism, sitting in a chair, could not hold his leg out straight as long as a normal person could

It is of interest to note that Dr Bartels has demonstrated by means of muscle biopsies that this

deals with thyroid disease in large numbers, that many men go through an entire medical lifetime without having to deal with such a case. Because any day such a case may arise in anyone's experience, I wish to present the dangers that occur in

FIGURE 14 Intractable Exophthalmos with Increasing Lid Pressure

The photograph on the right shows the relief from pressure obtained following unroofing of both bony orbital canals (reproduced from Poppen⁶ by permission of the publisher)

is a true muscular dystrophy (Fig 11). Figure 12 illustrates the change in the muscular state of the hands of a patient with hyperthyroidism preoperatively and postoperatively. As stated above, this is one of the real but unappreciated effects of the excessive metabolism in patients with hyperthyroid-

intractable exophthalmos and the measures that may be undertaken to prevent the loss of eyes in these patients.

It is important to remember that intractable exophthalmos is more frequently associated with myxedema, either postoperative, spontaneous or as

FIGURE 15 Steps in the Operation for Intractable Exophthalmos

ism who are permitted to remain untreated for a long time

Exophthalmos

It has always been of interest to me to present some of our experiences with intractable exophthalmos because I am sure, except in a group that

a result of thyroiditis, than with hyperthyroidism. Figure 13 presents an example of an intractable exophthalmos in which the left eye was needlessly lost and could have been saved, as was the right eye, had the condition been properly dealt with earlier.

Exophthalmos was shown by Naffziger⁵ to be the result of a myxomatous infiltration of the ocular

muscles and the retro-orbital fat, resulting in edema-
ous enlargement of the muscles and infiltration of
the retro-ocular fat and thus crowding the eye
forward and producing lid pressure on the conjunc-
tiva, with consequent loss of nutrition and with
ulceration and infection (Fig 13)

Up to ten years ago, we had seen eyes lost in 6
cases as the result of this condition. Since the
employment of the Naffziger operation by the
neurosurgeons of the Clinic, Drs Gilbert Horrax
and James L. Poppen, no eyes have been lost in
patients with intractable exophthalmos.⁶ Because

the periosteum of the orbit. There is a bulging of
the retro-orbital fat as soon as the periosteal cover-
ing over the orbital canal is opened. Figure 16
illustrates diagrammatically the anatomy of the
orbital canal, the segment of orbital plate to be
removed, the bulging of ocular muscles and retro-
orbital fat through the decompressed, unroofed,
orbital cavity and the projection of the eye pre-
operatively and its recession following decom-
pression.

Although this operation, devised by Naffziger,
will not abolish in many of the cases the unsightly

FIGURE 16 Diagrams Representing the Various Steps in Decompression of the Eyeball in Intractable Exophthalmos

of the serious danger to the eyes in patients with
extreme exophthalmos I wish particularly to urge
that, should there be any evidences of lid pressure,
as shown in Figure 14, which illustrates the pre-
operative state and postoperative result in such a
case, prompt measures should be undertaken by
means of orbital decompression to relieve this
pressure. Figure 15 demonstrates the method of
decompressing the orbital canal. After exposure,
the panetel bone flap is turned down, the frontal
lobe of the brain is turned up, the bony roof of the
orbit is rongeuired away and an incision is made in

exophthalmos, it will, if done in time, prevent ulceration,
infection and, if loss of blood supply has not
already taken place, save the eye. It will obviously
be of no value, however, to patients who are sent
for management at the stage shown in the left eye
in Figure 13.

Liver Function

In addition to the external results of the advanced
stage of hyperthyroidism shown in Figure 1, serious
nonvisible and often unappreciated effects are going

a patient with hyperthyroidism, sitting in a chair, could not hold his leg out straight as long as a normal person could

It is of interest to note that Dr Bartels has demonstrated by means of muscle biopsies that this

is a true muscular dystrophy (Fig 11) Figure 12 illustrates the change in the muscular state of the hands of a patient with hyperthyroidism preoperatively and postoperatively. As stated above, this is one of the real but unappreciated effects of the excessive metabolism in patients with hyperthyroid-

intractable exophthalmos and the measures that may be undertaken to prevent the loss of eyes in these patients

It is important to remember that intractable exophthalmos is more frequently associated with myxedema, either postoperative, spontaneous or as

FIGURE 15 Steps in the Operation for Intractable Exophthalmos
In a, through a parietal flap with the frontal lobe elevated, the bony roof of the orbit has been rongeur'd away and the incised orbital periosteum and the underlying fat are seen, in b there is upward bulging of retro-ocular fat and muscles, with relief of forward pressure on the eye

ism who are permitted to remain untreated for a long time

Exophthalmos

It has always been of interest to me to present some of our experiences with intractable exophthalmos because I am sure, except in a group that

a result of thyroiditis, than with hyperthyroidism. Figure 13 presents an example of an intractable exophthalmos in which the left eye was needlessly lost and could have been saved, as was the right eye, had the condition been properly dealt with earlier.

Exophthalmos was shown by Naffziger⁸ to be the result of a myxomatous infiltration of the ocular

with sixteen movements daily. It is to be noted, has been our experience and that of many others that following the administration of this material there is prompt control of the diarrhea. Lipocaic is a product of the alpha cells of the pancreas, proposed by Dragstedt,⁹ of Chicago, and

FIGURE 19 The Effect of Lipocaic on the Diarrhea associated with Hyperthyroidism. Note the return to a normal number of bowel movements within a week following the administration of this material (reproduced from Bartels⁸ by permission of the publisher)

has to do with fat metabolism. It has proved to be of great value in controlling the undesirable diarrheas often associated with thyroid crises, which make it

FIGURE 20 Photograph of a Specimen Showing the Origin of a Carcinoma within an Adenoma of the Thyroid Gland. Note the complete erosion of the capsule between the two arrows where the centrally originating carcinoma has extended to involve the parenchyma (reproduced from Lahey, Hare, and Warren¹⁰ by permission of the publisher)

impossible to manage these patients so long as such a large fluid and fuel loss continues

Cancer of the Thyroid

Cancer of the thyroid used to be considered a particularly depressing aspect of thyroid disease. This was largely because patients with this lesion were often not seen until extensive malignant processes involved the entire neck, with large, nodular and fixed masses.

To approach this subject from the proper point of view, it should be realized that practically all

FIGURE 21 A Drawing of Typical Lateral Aberrant Thyroid Masses

Note their glandlike structure and their location running up and down laterally to the internal jugular vein

thyroid cancers originate from two sources — fetal or embryonal adenomas (Fig 20) and aberrant thyroid glands (Fig 21). For practical purposes, nearly all thyroid cancer originates in a previously existing benign, true adenoma of the gland, the percentage of malignancy being greater in fetal or embryonal adenomas than in the true, fully differentiated adenomas. Figure 20 shows a cancer arising within the capsule of a thyroid adenoma, with invasion and destruction of the capsule. Graham,^{11, 12} a number of years ago, demonstrated that so long as the cancer is within the fibrous capsule of the adenoma there will be but rare metastases to lymph

on at the same time, among which depression of liver function pre-eminently causes death

Figure 17 illustrates the effect, as determined by Bartels,⁷ on the glycogenic function of the liver as demonstrated by hippuric acid excretion in relation

FIGURE 17 Hippuric Acid Excretion and Basal Metabolic Rate in Hyperthyroidism

This chart shows the effect on liver function, as determined by hippuric acid excretion, in patients with three types of hyperthyroidism. Note the relation of the depression of hippuric acid excretion to the elevation of the basal metabolic rate, and the return of both to normal following operation (reproduced from Bartels⁷ by permission of the publisher)

to the severity of the disease in the three groups and grades of hyperthyroidism, as well as the return of the glycogenic function to normal with the return of the metabolic rate to normal. It is to be noted that the degree of depression of this glycogenic function of the liver is quite accurately related to the depression of the metabolism and to the return to normal of the basal metabolic rate following subtotal thyroidectomy.

Figure 18 shows the correlated effects on serum albumin and total serum protein preoperatively and postoperatively following the restoration of the basal metabolic rate to a normal level in patients with hyperthyroidism.

It is of value to present these graphic illustrations of the unseen effects of hyperthyroidism on patients

who are permitted to maintain high basal metabolic rates over long periods, because of their relation to mortality. I have often observed in the past years, after having seen many patients die of hyperthyroidism before any operation could be performed, that thyroid deaths, associated with hyperthermia and jaundice, were more frequently the result of diminished liver function than that of the excessive metabolism on any other single structure in the body.

Lipocaic in the Diarrhea of Hyperthyroidism

Owing to the fact, as stated above, that family physicians and patients are less fearful of surgical

FIGURE 18 Percentage of Serum Albumin and Total Protein Levels below Normal before and after Operation. This chart demonstrates the effect of hyperthyroidism on the proteogenic function of the liver.

procedures for hyperthyroidism than they were in past years, few patients now present themselves to us for care in a state of thyroid crisis. Occasional patients, however, are still sent to the Clinic for management in a state of crisis, and among the conditions making these states most difficult to deal with is that of the diarrhea associated with hyperthyroidism. Bartels,⁸ who has been interested

TABLE 4 Possible Causes of Diarrhea in Hyperthyroidism

HYPERMOTILITY	
Direct action of thyroid secretion on the intestinal musculature	
Vagal stimulation by thyroid excretion	
Reduction in gastric acids	
Retarded intestinal absorption (primary or secondary)	
Altered pancreatic secretion	
Reduced hepatic function	
Altered adrenal function	

in this subject, has listed the possible causes of diarrhea in hyperthyroidism, one of the most probable of which is altered pancreatic secretion, which is known to exist in severe states of hyperthyroidism (Table 4).

Figure 19 demonstrates the effects of the administration of lipocaic to such a patient in crisis,

with sixteen movements daily. It is to be noted that this has been our experience and that of many others following the administration of this material. There is prompt control of the diarrhea. Lipocaic is a product of the alpha cells of the pancreas, proposed by Dragstedt,⁹ of Chicago, and

thyroid cancers originate from two sources — fetal or embryonal adenomas (Fig 20) and aberrant thyroid glands (Fig 21). For practical purposes, nearly all thyroid cancer originates in a previously existing benign, true adenoma of the gland, the percentage of malignancy being greater in fetal or embryonal adenomas than in the true fully differentiated adenomas. Figure 20 shows a cancer arising within the capsule of a thyroid adenoma, with invasion and destruction of the capsule. Graham,^{11, 12} a number of years ago, demonstrated that so long as the cancer is within the fibrous capsule of the adenoma there will be but rare metastases to lymph

nodes, such metastases as occur being of blood-borne variety, but that as soon as the growth has eroded the capsule and involved the true parenchyma of the thyroid gland, with its rich supply of lymphatics, early lymph-node metastases will ensue. This illustration is presented to re-emphasize that the best approach to the treatment of cancer of the thyroid gland — in spite of the fact that the incidence of malignant degeneration within these

Dr Ficarra and I¹³ reported the experience in the Clinic with 47 patients with lateral aberrant thyroid glands in which the tissue on removal showed papillary adenocarcinoma so frequently that I strongly believe that all lateral aberrant thyroid glands should be considered potentially cancerous.

Table 5 demonstrates that this type of cancer is of a relatively low grade since but two of the patients died of carcinoma. It is to be noted, however, that

FIGURE 22 The Various Normal and Abnormal Positions of the Recurrent Laryngeal Nerve (reproduced from Lahey¹³ by permission of the publisher)

adenomas is relatively small, perhaps not over 5 per cent — is to remove all discrete adenomas before they have become malignant or if they have become malignant, before the capsule of the adenoma has been eroded. Although a change in consistence, such as increasing firmness or increasing fixation, is an indication of possible malignant degeneration within these adenomas, I am convinced that all discrete adenomas, since their removal is not associated with any mortality, should be removed as soon as they are discovered and before malignant degeneration has taken place.

Figure 21 presents an example of lateral aberrant thyroid glands. In a recent article on this subject,

6 patients had recurrences, required reoperation and are well and that 3 are living with recurrences, one of whom has pulmonary metastases.

Lateral aberrant thyroid glands, originating as they do in the ultimobranchial bodies from the fourth pharyngeal pouch, are located as lateral glandlike tumors running up and down in front of and in relation to the sternomastoid muscle and internal jugular vein (Fig 21). They may be multiple glandlike structures or a single large tumor mass. They should, in our opinion, all be removed radically, and when on pathological section they prove to be papillary adenocarcinomas, they should be treated radically by block dissection of the neck,

consisting of removal of the entire internal jugular vein from the mastoid to the clavicle, together with the entire front half of the sternomastoid muscle, all the adjacent lymph nodes and all the thyroid lobe on that side

It is important in these cases to remove the thyroid lobe on the same side when papillary adenocarcinoma occurs in lateral aberrant glands because of the possibility of division between the aberrant gland originating in the

the artery by severing the artery (c), and its fusion with the trachea in intrathoracic goiter from being pressed against the trachea (d) The recurrent laryngeal nerve often does not descend into the larynx but crosses from the vagus directly into the larynx (e) or descends as far as the inferior thyroid and then ascends to enter the larynx (f) There are two different types of extralaryngeal division of the recurrent laryngeal nerve into its adductor and abductor fibers (g and h)

It has been taught to every surgeon in the Clinic that exposure of the recurrent laryngeal nerve, which is not difficult, not only adds to the preservation of the vocal-cord innervation by avoiding injury

TABLE 5 Data in 47 Cases with Lateral Aberrant Thyroid Glands

CONDITION OF PATIENT	CASES BEFORE 1939	CASES SINCE 1939

ultimobranchial bodies with the true gland often results in the inclusion of malignant degeneration within the associated lobe of the thyroid gland itself This probably explains why in these cases papilliferous aberrant thyroid nodules similar to those lateral to the thyroid gland are occasionally found within the substance of the thyroid gland

Table 6 presents a five-year follow-up study of 231 patients with cancer of the thyroid gland, in-

TABLE 6 Five-Year Survival in 231 Cases of Carcinoma of the Thyroid Gland

cluding the different types of malignancy, with their five-year survival rates¹ As will be seen from these figures, which represent the treatment of thyroid cancer by radical removal followed by intensive irradiation, this condition is by no means as hopeless as it was formerly thought to be

Recurrent-Nerve Paralysis and Preservation of Parathyroid Glands

Some years ago I¹⁴ suggested that the recurrent laryngeal nerve be dissected and demonstrated in every patient operated on for thyroid disease Figure 22 demonstrates the usual and the unusual positions of the recurrent laryngeal nerve It shows the relation of the nerve to the inferior thyroid artery, either before or behind it (a and b), the methods of exposing the nerve when it is behind

FIGURE 23 Roentgenogram of a Large Intrathoracic Goiter Obviously, this intrathoracic mass could not have been made to pass through the upper thoracic strait It is in this type of intrathoracic goiter that breaking down the center of the goiter to collapse it makes it possible to deliver the mass without removing a portion of the chest wall or the clavicle

to the nerve but also, because the complete anatomy of the thyroid gland is exposed, permits more radical removal of thyroid tissue, since one knows where the nerve and the parathyroid glands are and can thus avoid leaving behind large sections of the gland to protect these structures, as when the nerves are not demonstrated and visualized

The technical step of demonstration of the inferior thyroid artery and the recurrent laryngeal nerve has in addition made it possible to find in

practically every patient operated on for thyroid disease in the Clinic at least two parathyroid glands. It is now our belief that practically no thyroid operation should be done in which it cannot be demonstrated that two parathyroid glands with a good blood supply have been preserved, thus avoiding the possibility of one of the most undesirable com-

with thyroid operations to dissect and expose even recurrent laryngeal nerve in every patient operated on in the Clinic for thyroid disease, to be certain that the nerves are preserved.

Intrathoracic Goiter

Figure 23 illustrates a typical, large, intrathoracic goiter. Figure 24 shows the specimen of such an intrathoracic goiter after removal, and Figure 25 the deviation of the trachea in such an intrathoracic goiter. Figure 26 demonstrates the compression effect on the trachea, resulting in diminution in caliber to a half in such an intrathoracic goiter. In Figure 27 is shown an infrared photograph of a patient before the removal of a large intrathoracic goiter to demonstrate the effect on compensatory

FIGURE 24 Photograph of a Large Extrathoracic and Intrathoracic Goiter

The small portion above is the extrathoracic goiter, and the large mass below the intrathoracic goiter (see Fig. 23)

FIGURE 25 The Effect on the Trachea of a Large Intrathoracic Goiter

Note the marked forward deviation of the trachea

plications that occasionally occur with subtotal thyroidectomy for hyperthyroidism—that is, tetany.

Paralysis of the recurrent laryngeal nerve is not serious when but one nerve is injured, since the vocal cords on the uninjured side will overcompensate to provide a reasonably good voice, and there will usually remain a reasonably adequate glottic space for breathing. When, however, both recurrent laryngeal nerves are injured, eventual fibrosis of the vocal cords, together with arytenoid fixation, results in such a narrowing of the glottic space that there is an inadequate airway for the intake of a sufficient amount of oxygen to meet the demands of only moderate physical activity. It has, therefore, proved worth while in this large experience

venous circulation in the superficial thoracic veins brought about by the pressure of an intrathoracic goiter on the internal jugular veins, interfering with the return venous flow from the head. One should note the enormous dilatation of the superficial thoracic veins as compared with the normal superficial thoracic venous circulation.

When one considers the diameter of such an intrathoracic goiter, it becomes obvious that such an intrathoracic tumor cannot be made to pass through the upper thoracic strait because its diameter is so much greater than that of the strait. It is in such

es that I wish particularly to call attention to the fact that it is not necessary to remove ribs or to divide the clavicle in an attempt to enlarge the upper thoracic aperture so that an intrathoracic tumor of this diameter can be made to pass through it. By ligating the superior and inferior thyroid arteries, together with the venous connections of the thyroid to the internal jugular vein, it is possible completely to devascularize this intrathoracic tumor, and to make an incision into the capsule, insert a finger

before an attempt is made to remove such an intrathoracic goiter from the chest, to introduce a rigid-walled, flexible intratracheal tube into the trachea under direct laryngoscopy so that the manipulations necessary for the removal of such an intrathoracic goiter do not result in compression of the trachea and produce such interference with respiration and anesthesia that they cannot be maintained.

A great many patients have been operated on in the Clinic with completely intrathoracic goiters

FIGURE 26 *The Compression Effect on the Trachea of a Large Intrathoracic Goiter*
Note the reduction of the caliber of the trachea to one half to one third its normal size

into the center of the semisoft mass, break its center down, suck out its semiliquid contents, separate its capsule from the surrounding pleura and gradually deliver the entire tumor through the upper thoracic strait without enlarging that aperture.

In Figure 26, in which the caliber of the trachea has been reduced to approximately one third the normal size by the pressure of the intrathoracic goiter, it can be demonstrated how necessary it is

large enough to require extensive manipulative measures within the thorax in which the compression of the trachea has been of such extent that an intratracheal tube could not be introduced under a general anesthesia, such an anesthesia would have resulted in choking from closing of the small remaining tracheal airway. In such cases it has been possible for our anesthetists to introduce the intratracheal

tube first into the cocainized larynx and then to induce general anesthesia safely

It is to be noted that the effect of an intrathoracic goiter is not only one of pressure on the trachea to interfere with breathing but also one of pressure on

a previously obvious thyroid tumor in the neck but disappeared one should seriously consider the possibility that it has descended into the superior mediastinum, that an adenomatous goiter whose lower pole cannot be felt should seriously be considered to have become intrathoracic, and that in any patient with a large intrathoracic goiter disappearing beneath the clavicle, x-ray films should be taken particularly directed toward demonstrating the trachea to determine whether or not there is deviation of the trachea by an intrathoracic goiter and an extension of the goiter into the mediastinum.

Finally, all adenomatous enlargements of the thyroid gland that tend to extend beneath the clavicle should be removed before they become intrathoracic goiters of such magnitude as those illustrated in Figures 23, 24 and 25

* * *

This paper represents a review of thirty years' experience with the surgery of the thyroid gland. In it are discussed some of the newer developments and some of the less frequent complications of thyroid disease as seen in a clinic dealing with these states in large numbers of cases

CLINICAL NOTES

VISCERAL LEISHMANIASIS*

REPORT OF A CASE

SYDNEY P. WAUD, M.D.,† AND SAM KRUGER, M.D.‡

HINES, ILLINOIS

VISCERAL leishmaniasis (kala-azar) in American personnel returning to the United States has been rare. Burchenal and Woods§ reported 3 cases in American troops who had contracted the disease in the Mediterranean area. It is estimated that approximately 60 cases of the disease have occurred in American troops during World War II, the majority of which were contracted in the India-Burma Theater. The endemic areas where American personnel have been stationed are India, North Africa, Sicily, Southern Italy, Manchuria and China.

Visceral leishmaniasis is an infective disease that is characterized by fever, splenomegaly and usually hepatomegaly, as well as by a loss of weight and leukopenia, generally running a chronic course. Since the incubation period varies from six days to six months and since the course of the disease may last a year and a half, the total time from the inception to the termination of the disease is approximately two years. This is definitely of importance, since the soldier may have time to become a civilian and manifest the symptoms of the disease long after his return to the United States.

It is believed that this disease is worthy of attention because, if untreated, it is fatal in 90 per cent of cases, whereas prompt diagnosis and treatment ensure recovery in approximately 95 per cent.

K. P., a 22-year-old veteran, was admitted to the hospital on February 8, 1946, complaining of chills, fever and a mild headache. The patient had been stationed in and around Calcutta, India, for 2 years and had returned to the United States in December, 1945. He had not been on suppressive quinacrine (Atabrine) therapy and had not had malaria. There was nothing of significance in the family history, all members of the immediate family being well. The patient himself had been well until the onset of the present illness, which had begun during the 3rd week in December, while he was en route home from India. He noticed at first a chilliness followed by a slight fever every evening. He stated that he had reported to the sick bay, where he was treated for an upper respiratory infection. After arrival in the United States he was discharged from the Army, apparently, little or no evidence of the illness was present at that time, and the final Army physical examination was negative. The patient stated that the symptoms increased somewhat in severity on about January 1, but that he still did not feel

sick enough to consult a physician. In the middle of January, however, at his mother's insistence, he consulted a physician. The patient was placed on bed rest and given a high-calorie diet and some medication, which he believed to be a "tonic." All symptoms gradually subsided, and the patient felt well enough to make a trip away from home. Early in February, however, there was an exacerbation of symptoms, and actual chills, with high temperatures, occurred. Occasional mild headaches were also noted. The patient stated that he had lost about 15 pounds since the onset of the illness.

Physical examination revealed a poorly developed and poorly nourished man, who did not appear acutely ill. The temperature was 104°F, the pulse 126, and the respirations 24. The blood pressure was 110/75. The head was of normal configuration. The scalp, ears, eyes and nose were normal. There was a fine tremor of the tongue. The pharynx was not injected. There was no cervical adenopathy and no stiffness or other abnormality of the neck. The thyroid gland was not palpable. The chest was symmetrical, with prominent costochondral junctions. Tactile fremitus, resonance and breath sounds were normal throughout. There were no rales or adventitious sounds. The heart borders were within normal limits, there were no murmurs. The abdomen was flat, with no tenderness. The spleen was palpable 3 cm. below the costal margin, but the liver was not palpable. The extremities showed no limitation of motion, but all limbs had a fine tremor on motion. The axillary lymph nodes were not palpable, and the inguinal lymph nodes were not enlarged. The skin was clear, except for a suggestion of pigmentation along the lateral inferior orbital aspects. The reflexes were normal throughout.

Examination of the blood revealed a red-cell count of 4,630,000, with a hemoglobin of 90 per cent and a white-cell count of 5500. During the next 18 days the red-cell count gradually fell to 2,640,000, the hemoglobin to 52 per cent and the white-cell count to 3750. The differential count showing a marked shift to the left. During the same period the sedimentation rate rose from 8 to 29 mm. per hour. Repeated smears for malarial parasites were negative, as were blood serologic studies. Agglutination tests for the organisms of typhoid, paratyphoid, typhus and undulant fever were negative. Roentgenograms of the chest were normal. Urinalyses were negative. The total blood protein was 8.4 gm. per 100 cc., with 4.8 gm. of albumin and 3.6 gm. of globulin. The thymol-turbidity test was 19 units, the cephalin-flocculation test was + + + +, and the icterus index was 8.2. Blood smears and blood cultures (some on NNN mediums) were negative. Marrow smears and cultures were negative for organisms. Gross and microscopic study of the axillary lymph nodes revealed no pathologic changes. Formol-gel tests showed solidification and opacity at the end of 3 hours. Smears from a splenic puncture performed on March 8 revealed typical Leishman-Donovan bodies within endothelial leukocytes. The antimony serum test (performed after the patient had received 0.6 gm. of Neostibosan) was negative.

Although malarial parasites could not be demonstrated, the clinical course resembled that of malaria, and the patient was therefore given a therapeutic trial of quinacrine. The skin became markedly yellow, but there was no improvement. After 10 days of hospitalization the patient was given 240,000 units of penicillin daily for 3 days, but there was no alleviation of symptoms. By that time the spleen was palpated 7 cm. below the costal margin. The liver became palpable, and a small group of lymph nodes in the left axilla became palpable. The patient lost 4 pounds in weight despite a fair appetite and a high-calorie diet. The temperature continued to show a septic rise, varying between 102 and 104°F. Day and night 4-hour temperature readings were started, and it was noted that frequently there was a second elevation during the 24-hour period. A transfusion of 500 cc. of whole blood was given during the last week of February, and another was given during the 1st week in March.

When the diagnosis of visceral leishmaniasis was confirmed by demonstration of the organisms in the splenic pulp, specific antimony therapy was instituted. A total of 4.2 gm. of Neostibosan in fifteen divided doses was given intravenously over a period of 15 days. Within 48 hours the temperature was reduced to nearly normal limits, the appetite improved remarkably, and the profuse perspiration stopped. The spleen in the area of the puncture remained

¶Burchenal, J. H. and Woods, R. P. Visceral leishmaniasis: report of three cases of its occurrence in members of armed forces of United States. *War Med.* 7: 173-177, 1945.

tender During the following 2 days the splenic tenderness increased, with a concomitant increase in the temperature, which at one time reached 102°F. This splenic tenderness was believed to be caused by a small, traumatic, subcapsular hemorrhage. Within 2 days the perisplenitis decreased slowly until the pain entirely disappeared within a month. The spleen decreased slowly in size but remained palpable at the end of 1 month of treatment. The pigmentation around the eyes was no longer detected at that time. On March 27 examination of the blood revealed a red-cell count of 4,160,000, with a hemoglobin of 80 per cent, and a white-cell count of 9000, the sedimentation rate was 20 mm per hour. The gain in appetite, weight and strength was steady, and the patient was discharged from the hospital on April 13.

A case of visceral leishmaniasis (kala-azar) is reported.

The possibility of visceral leishmaniasis should be considered in patients with fever of undetermined origin, leukopenia and splenomegaly who have resided in an endemic area.

CO-EXISTENT PRIMARY CARCINOMA OF THE FALLOPIAN TUBE AND OF THE BREAST

REPORT OF A CASE

JOHN F. CURRAN, M.D.,* AND
EDWARD A. KILROY, M.D.†

WORCESTER, MASSACHUSETTS

THE purpose of this paper is to discuss primary carcinoma of the fallopian tube, and to submit a report of the first case at the Worcester City Hospital of carcinoma of the fallopian tube and carcinoma of the breast in the same patient. As in the vast majority of cases reported in the literature, the diagnosis of tubal carcinoma was not made preoperatively. It was only suspected during the operation for another pelvic disorder and was confirmed by routine pathological study of the tissues removed during the operation.

Since Rokitsky's original pathological description in 1861 and the first accredited case report presented by Orthmann in 1886, only 449 cases of primary carcinoma of the fallopian tube have been reported in the literature, according to a recent review by Mitchell and Mohler¹. From figures presented by various clinics these authors estimate that the incidence of the disease among genital-tract tumors is 0.5 per cent, secondary carcinoma of the fallopian tube being about ten times more frequent. The extreme difficulty in diagnosis without pathological studies of the diseased tubes has been discussed by many authors, and it is only with this fact in mind that Martzloff,² allowing for unreported as well as unrecognized cases, estimates the upper limit of incidence of primary tubal cancer to be about 0.5 per cent.

The importance of a serous or serosanguineous discharge from the cervix as a diagnostic aid in this disease has been emphasized by numerous authors.^{2,3} Martzloff² states that if recent gestation and disease of the vagina and uterine cavity—especially incipient ulcerating cancer complicated by cervical stenosis—can be excluded, a copious, serosanguineous uterine discharge becomes suspiciously pathognomonic and can be ascribed to an extrauterine origin, logically tubal, and a malignant complication. The symptom complex of an otherwise unexplained intermittent, cramplike, abdominal discomfort relieved by the passage of a watery discharge from the vagina, especially when blood tinged, has been considered to be of diagnostic value by several authors, including Martzloff² and Mitchell and Mohler¹. A further adjunct in diagnosis lies in hystero-graphy, whose value and advisability have been debated by different authors.

The treatment of primary tubal carcinoma consists in surgery, with or without postoperative radium or x-ray therapy. Although Martzloff² considered bilateral salpingo-oophorectomy and pan-hysterectomy the operation of choice and believed that there was no evidence that radium and irradiation were of value, other authors have taken exception to his opinions. Keith⁴ proposed the surgical removal of both tubes and ovaries and all pathologic tissue except the uterus, which is left in situ as a receptacle for radium. He believed that good surgery, in addition to the immediate postoperative use of radium implantation and irradiation, would save a larger percentage of patients than either surgery or x-ray therapy alone.

J. H. (W.C.H. 34082), a 50-year-old Negro, was first admitted to the hospital on September 9, 1945, complaining of intermittent pains in the right lower quadrant and of a lump in the left breast. The abdominal pains, which had occurred at occasional intervals for 5 or 6 years, dating back approximately to the time of the menopause, were described as sharp, intermittent and lasting from 2 to 5 minutes and were unassociated with any genitourinary or gastrointestinal complaints or with any change in position or motion. During the 6 weeks before entry these pains had become more frequent, occurring several times a day, occasionally being associated with slight nausea but never with vomiting. The mass in the left breast had first been noted approximately 2 years before entry. It had grown slowly in size and had produced no symptoms. The patient also complained of occasional low-back aches. She denied any weight loss, anorexia or vaginal discharge.

The family history was extremely interesting in that 5 relatives of her father had died of cancer—1 of carcinoma of the stomach, 2 of carcinoma of the breast and 2 of carcinoma of the rectum.

Physical examination was essentially negative with the exception of the left breast, the abdomen and the pelvis. In the upper and outer quadrant of the left breast there was a palpable, tangerine-sized mass, which was firm, nontender and firmly attached to the adjacent glandular structures and to the overlying skin. There was no bleeding or discharge from the nipple. Palpation of the abdomen revealed a round, firm, nontender grapefruit-sized mass in the left lower quadrant. The right vault was normal, but in the left vault the mass described above could be palpated. On bimanual examination a hard solid mass was palpated in the region of the uterus.

*Visiting surgeon Worcester City and Belmont hospitals, Worcester.
†Surgical house officer Worcester City Hospital.

Laboratory examination was essentially negative except for a red-cell count of 3,700,000 and hemoglobin of 68 per cent.

On September 14 the patient was operated on with a preoperative diagnosis of fibroid uterus, left ovarian cyst and carcinoma of the left breast. Palpation of the abdomen disclosed that the large tumor on the left extending upward to the umbilicus had disappeared. The fibroid uterus, however, as well as the palpable. Through the usual abdominal incision the peritoneum was opened, and a large amount of pus-like material was escaped. The uterus was observed to be adherent to the peritoneum throughout the lower half of the abdomen. The fluid was aspirated; the uterus was elevated and found to contain numerous subserous fibroids varying in size, the largest being at the fundus. This was used as a sentinel, and a large ruptured ovarian cyst was delivered by blunt and sharp dissection from the left broad ligament. The left tube presented a large hydrosalpinx. Both the broad ligament and tube were double clamped distally, and their distal ends were clamped and divided, the mass being removed in toto. A suprapubic hysterectomy was then performed in the usual manner. Following the abdominal opening the tumor of the left breast was removed, together with a large portion of breast tissue. The patient had an uneventful course following this operation.

Some microscopic studies of the breast tumor revealed a primary carcinoma, a left radical mastectomy was performed on the 10th postoperative day. Again the postoperative course was uneventful with the exception of the anemia, which was treated with iron and whole-blood transfusions. The patient was discharged on the 22nd hospital day. After discharge the patient felt well, gradually regained strength and had gained 8 pounds when last seen, 5 months following the first operation.

Gross pathological inspection revealed a funnel-shaped mass measuring 12 by 1.5 by 0.5 cm., with a dull and shaggy surface. The wall was thick and fibrous, at one point measuring 1.5 cm. in thickness. The specimen showed yellow-gray areas resembling caseation. The tumor of the breast measured 12 by 8 by 4 cm., with a deeply pigmented, roughy cut surface, a piece of skin measuring 3 by 2.5 cm. On section the specimen showed a mottled dense yellow-gray surface sharply demarcated from the circumferential tissue. The rest of the breast tissue was abundant, gray and firm.

Microscopic examination of the tube disclosed a soft mass of tumor cells filling the lumen without any attempt at gland formation. Under high-power inspection these cells had an irregular cell membrane. The nuclei were mostly oval and vesicular, with rare nucleoli. Many mitoses and a few stroma cells were seen.

The breast showed strands of tumor cells with little stroma. The cells had poorly staining cytoplasm and dark nuclei. Few mitoses were present. In some areas there were wreaths of consecutive cells.

The diagnosis was primary carcinoma of the fallopian tube and primary medullary carcinoma of the breast.

From a pathological point of view, attention should be drawn to the difficulty in differentiating tuberculosis and carcinoma of the tube. The former pinches off tiny groups of epithelial cells of the mucosa in such a way that they may present a picture that simulates carcinoma. In all cases of tubal carcinoma a search for the giant cells of tuberculosis is therefore essential.

* * *

A few of the more important considerations regarding the incidence, diagnosis and treatment of primary carcinoma of the fallopian tube are discussed.

A report of the first case of this disease diagnosed in this hospital is presented in which the rare primary tubal carcinoma was associated with a primary carcinoma of the breast in a patient whose family history included 5 cases of deaths due to

cancer. Although 30 per cent of cases of primary carcinoma of the fallopian tube are bilateral inasmuch as the diagnosis was made only by routine pathological examination of tissue removed at operation for a fibroid uterus and ovarian cyst, and also because the case was further complicated by a second major operation, a radical mastectomy, it was not deemed advisable to subject the patient to further surgery. X-ray and radium therapy were not given the patient.

COMPLETE ABSENCE OF LOCHIA FOLLOWING DELIVERY*

REPORT OF A CASE

ROY J. HEFFERNAN, M.D.,[†] AND CHARLES LEAVITT SULLIVAN, M.D.[‡]

BROOKLINE, MASSACHUSETTS

THE characteristic bloody discharge that follows childbirth has always been considered such a fundamental phenomenon of parturition that it is designated by the word "lochia," derived from a Greek word meaning "woman in childbirth." Complete absence of lochial discharge following the birth of a viable infant has not, to our knowledge, been reported. In 1922 Kickham¹ reported the case of a patient delivered by cesarean section in which there was no grossly demonstrable cervix or cervical opening, there was no sign of vaginal discharge until fifteen hours post partum, when a thin serous fluid, which gradually became blood stained, appeared and continued to be discharged intermittently until the patient left the hospital twenty-two days later. Sperling² noted that involution occurred more quickly following cesarean section and believed this to be due to a diminished wound surface—in cesarean section only the body of the uterus is wounded whereas in delivery through the pelvis the factors of trauma to the cervix and to the vagina are added. DeLee,³ commenting on Sperling's article, states, "The small amount of lochia after cesarean section is remarkable; indeed one often suspects lochiostasis, and attempts unnecessary drainage." Bardenheuer, who is quoted by Sperling as making the same observation, considered the paucity of lochia to be due

tender. During the following 2 days the splenic tenderness increased, with a concomitant increase in the temperature, which at one time reached 102°F. This splenic tenderness was believed to be caused by a small, traumatic, subcapsular hemorrhage. Within 2 days the perisplenitis decreased slowly until the pain entirely disappeared within a month. The spleen decreased slowly in size but remained palpable at the end of 1 month of treatment. The pigmentation around the eyes was no longer detected at that time. On March 27 examination of the blood revealed a red-cell count of 4,160,000, with a hemoglobin of 80 per cent, and a white-cell count of 9000, the sedimentation rate was 20 mm per hour. The gain in appetite, weight and strength was steady, and the patient was discharged from the hospital on April 13.

A case of visceral leishmaniasis (kala-azar) is reported.

The possibility of visceral leishmaniasis should be considered in patients with fever of undetermined origin, leukopenia and splenomegaly who have resided in an endemic area.

CO-EXISTENT PRIMARY CARCINOMA OF THE FALLOPIAN TUBE AND OF THE BREAST

REPORT OF A CASE

JOHN F. CURRAN, M.D.,* AND
EDWARD A. KILROY, M.D.†

WORCESTER, MASSACHUSETTS

THE purpose of this paper is to discuss primary carcinoma of the fallopian tube, and to submit a report of the first case at the Worcester City Hospital of carcinoma of the fallopian tube and carcinoma of the breast in the same patient. As in the vast majority of cases reported in the literature, the diagnosis of tubal carcinoma was not made preoperatively. It was only suspected during the operation for another pelvic disorder and was confirmed by routine pathological study of the tissues removed during the operation.

Since Rokitsansky's original pathological description in 1861 and the first accredited case report presented by Orthmann in 1886, only 449 cases of primary carcinoma of the fallopian tube have been reported in the literature, according to a recent review by Mitchell and Mohler.¹ From figures presented by various clinics these authors estimate that the incidence of the disease among genital-tract tumors is 0.5 per cent, secondary carcinoma of the fallopian tube being about ten times more frequent. The extreme difficulty in diagnosis without pathological studies of the diseased tubes has been discussed by many authors, and it is only with this fact in mind that Martzloff,² allowing for unreported as well as unrecognized cases, estimates the upper limit of incidence of primary tubal cancer to be about 0.5 per cent.

The importance of a serous or serosanguineous discharge from the cervix as a diagnostic aid in this disease has been emphasized by numerous authors.^{3,4} Martzloff² states that if recent gestation and disease of the vagina and uterine cavity — especially incipient ulcerating cancer complicated by cervical stenosis — can be excluded, a copious, serosanguineous uterine discharge becomes suspiciously pathognomonic and can be ascribed to an extrauterine origin, logically tubal, and a malignant complication. The symptom complex of an otherwise unexplained intermittent, cramplike, abdominal discomfort relieved by the passage of a watery discharge from the vagina, especially when blood tinged, has been considered to be of diagnostic value by several authors, including Martzloff² and Mitchell and Mohler.¹ A further adjunct in diagnosis lies in hystero-graphy, whose value and advisability have been debated by different authors.

The treatment of primary tubal carcinoma consists in surgery, with or without postoperative radium or x-ray therapy. Although Martzloff² considered bilateral salpingo-oophorectomy and pan-hysterectomy the operation of choice and believed that there was no evidence that radium and irradiation were of value, other authors have taken exception to his opinions. Keith⁴ proposed the surgical removal of both tubes and ovaries and all pathologic tissue except the uterus, which is left in situ as a receptacle for radium. He believed that good surgery, in addition to the immediate postoperative use of radium implantation and irradiation, would save a larger percentage of patients than either surgery or x-ray therapy alone.

J. H. (WCH 34082), a 50-year-old Negress, was first admitted to the hospital on September 9, 1945, complaining of intermittent pains in the right lower quadrant and of a lump in the left breast. The abdominal pains, which had occurred at occasional intervals for 5 or 6 years, dating back approximately to the time of the menopause, were described as sharp, intermittent and lasting from 2 to 5 minutes and were unassociated with any genitourinary or gastrointestinal complaints or with any change in position or motion. During the 6 weeks before entry these pains had become more frequent, occurring several times a day, occasionally being associated with slight nausea but never with vomiting. The mass in the left breast had first been noted approximately 2 years before entry. It had grown slowly in size and had produced no symptoms. The patient also complained of occasional low-back aches. She denied any weight loss, anorexia or vaginal discharge.

The family history was extremely interesting in that 3 relatives of her father had died of cancer — 1 of carcinoma of the stomach, 2 of carcinoma of the breast and 2 of carcinoma of the rectum.

Physical examination was essentially negative with the exception of the left breast, the abdomen and the pelvis. In the upper and outer quadrant of the left breast there was a palpable, tangerine-sized mass, which was firm, nontender and firmly attached to the adjacent glandular structures and to the overlying skin. There was no bleeding or discharge from the nipple. Palpation of the abdomen revealed a round, firm, nontender grapefruit-sized mass in the left lower quadrant. The right vault was normal, but in the left vault the mass described above could be palpated. On bimanual examination a hard solid mass was palpated in the region of the uterus.

laboratory examination was essentially negative except a red-cell count of 3,790,000 and hemoglobin of 68 per cent. On September 14 the patient was operated on with a pre-operative diagnosis of fibroid uterus, left ovarian cyst and carcinoma of the left breast. Palpation of the abdomen disclosed that the large tumor on the left extending upward to the umbilicus had disappeared. The fibroid uterus however was still easily palpable. Through the usual subumbilical incision the peritoneum was opened, and a large amount of chocolate-colored fluid escaped. The omentum was observed to be adherent to the peritoneum throughout the lower half of the abdomen. The fluid was syphoned, the uterus was elevated and found to contain numerous subserous fibroids varying in size, the largest being at the fundus. This was used as a nodule and a large ruptured ovarian cyst was delivered blunt and sharp dissection from the left broad ligament. The left tube presented a large hydrophalus. Both the broad ligament and tube were double clamped distally, and their proximal ends were clamped and divided, the mass being removed in toto. A supravaginal hysterectomy was then performed in the usual manner. Following the abdominal operation the tumor of the left breast was removed, together with a large portion of breast tissue. The patient had an uneventful course following this operation.

Since microscopical studies of the breast tumor revealed a primary carcinoma, a left radical mastectomy was performed on the 10th postoperative day. Again, the post-operative course was uneventful with the exception of the anemia, which was treated with iron and whole-blood transfusions. The patient was discharged on the 23rd hospital day. After discharge the patient felt well, gradually regained strength and had gained 8 pounds when last seen, 5 months following the first operation.

Gross pathological inspection revealed a funnel-shaped tube measuring 12 by 2.5 by 0.5 cm., with a dull and shaggy serosa. The wall was thick and fibrous, at one point measuring 1.5 cm. in thickness. The specimen showed yellow-gray necrosis resembling caseation. The tumor of the breast measured 12 by 8 by 4 cm., with a deeply pigmented, roughly elliptical piece of skin measuring 3 by 2.5 cm. On section this specimen showed a mottled, dense, yellow-gray surface sharply demarcated from the circumferential tissue. The rest of the breast tissue was abundant, gray and firm.

Microscopic examination of the tube disclosed a solid mass of tumor cells filling the lumen, without any attempt at gland formation. Under high-power inspection these cells had an indistinct cell membrane. The nuclei were mostly oval and vesicular, with rare nucleoli. Many mitoses and a few stroma cells were seen.

The breast showed strands of tumor cells with little stroma. The cells had poorly staining cytoplasm and dark nuclei. Few mitoses were present. In some areas there were wide bands of connective tissue.

The diagnoses were primary carcinoma of the fallopian tube and primary medullary carcinoma of the breast.

From a pathological point of view, attention should be drawn to the difficulty in differentiating tuberculosis and carcinoma of the tube. The former pinches off tiny groups of epithelial cells of the mucosa in such a way that they may present a picture that simulates carcinoma. In all cases of tubal carcinoma a search for the giant cells of tuberculosis is therefore essential.

to acidosis and mentioned an attempt to control the amount of lochia by diet

In the following case, in which the patient was delivered by cesarean section at thirty-six weeks because of toxemia, a contracted pelvis, elderly primiparity and a breech presentation, there was no vaginal discharge during the twenty-one days of an otherwise normal postoperative and puerperal course. During that time the temperature rose above normal on three scattered occasions, but never above 99.4°F

Mrs. C, a 40-year-old primigravida, was first seen during the 12th week of pregnancy. There had been no serious illnesses and no operations. The periods, which had begun at the age of 12 years, occurred regularly every 28 days, but the flow for the preceding 10 years had been scanty and of only 2 days' duration. The last regular period had begun on July 24, 1944. Physical examination revealed no abnormalities. The blood pressure was 138/86, and urinalysis was negative.

The pregnancy continued uneventfully until the 34th week of gestation, when there was an elevation of blood pressure to 142/110, urinalysis revealed the smallest possible trace of albumin, and there was slight edema of the hands and ankles. The patient was treated at home for a week with bed rest, mild sedation, a salt-free diet and saline catharsis. This treatment brought no improvement, and the patient was admitted to the Cardinal O'Connell House, St. Elizabeth's Hospital. The blood pressure was then 150/114. The urine showed a trace of albumin, and the edema had increased. After a week of complete bed rest, sedation, saline purgation and intravenous hypertonic dehydration, the blood pressure had risen to 178/114. The patient became irritable and apprehensive, and there was upper abdominal distress and headache. She was then 36 weeks pregnant. The fundus was palpated 3 fingerbreadths below the ensiform. The fetus was in the left sacroanterior position, with the breech in the false pelvis. The pelvic outlet was narrow, and the cervix long and firm.

On March 31, 1945, after a transverse cervical cesarean section under spinal anesthesia, a female infant weighing 4 pounds, 14 ounces was delivered. The infant was otherwise normal in all respects and was discharged from the hospital in 35 days, weighing 5 pounds, 9 ounces. The infant was not breast fed. One ampule of ergot was administered intramuscularly following delivery. The intravenous route was not used because of the mother's hypertension. The placenta and membranes were expressed intact after they had begun to separate.

On the following day the blood pressure had dropped to 114/96. The temperature was 99.4°F, the pulse 84, and the respirations 20. There was no nausea or vomiting. The edema had disappeared, the patient felt well and was excreting a normal amount of urine. Since returning from the operating room there had been absolutely no lochial discharge. The fundus was nontender and firm, and could be felt 1 fingerbreadth below the umbilicus. The temperature on the 1st, 4th and 10th post-partum days was slightly elevated, the highest reading was 99.4°F. The postoperative course was otherwise entirely uneventful. The patient was allowed out of bed on the 7th postoperative day.

There was no distention and no elevation of pulse or respirations. The vulval pads were carefully inspected and remained perfectly dry until discharge from the hospital. The fundus, which was felt each day, continued to be nontender, and involution progressed normally, so that the fundus was felt 3 fingerbreadths above the symphysis on the 12th post-partum day. The patient was discharged on the following day, when the blood pressure was 120/90 diastolic.

On the 21st day following delivery, menstrual flow began. The amount of flow was slightly more profuse and lasted 1 day longer than the usual period. The flowing was painless, and there were no clots. On examination, 4 weeks after delivery, the fundus was in anterior position, and was $\frac{1}{2}$ larger than normal. There was no vaginal discharge, and the general condition was excellent. Two weeks later the uterus was normal in size and position. There was no discharge, and the urine was normal. The blood pressure was 124/84.

Fifteen weeks after delivery, the blood pressure was 128/78, urinalysis was negative, the fundus was normal in size and position, and the patient felt well. The periods, which were scanty and of 2 days' duration, had occurred regularly at 28-day intervals.

Involution, the change in the size of the uterus following delivery, is one of the most striking examples of atrophy known. The average post-partum uterus is said to weigh in the vicinity of $2\frac{1}{2}$ pounds, or 1000 gm,⁴ half as much a week later, from 350 to 375 gm at two weeks and 50 gm when normally involuted at six or seven weeks. The structures involved in this process are the muscle fibers, the blood vessels and the decidua, especially at the placental site. The amount of lochia has been variously estimated as between 500 and 1000 cc,⁵ although we have found no record of accurate measurement, during the first three days it is said to be profuse enough to soak a perineal pad in six to eight hours.⁶ The bloody discharge is generally believed to last from ten days to two weeks.

Knowledge concerning the processes of regeneration of the uterine mucosa following labor may be said to have begun with the monograph of Friedlander,⁷ written in 1870, although William Hunter,⁸ a century earlier, had stated that "the decidua is an efflorescence of the inner coat of the uterus, and is therefore shed as often as the woman bears a child or suffers a miscarriage." In 1931 Williams⁹ described in detail the regeneration of the uterine mucosa following delivery, he stated that the cervical mucosa is not cast off and is completely restored by the end of the first week post partum, although the tissue beneath it may long remain infiltrated with blood, he also observed that, at the end of fourteen days, the uterine cavity is completely covered by endometrium and that by the third week the uterine mucosa is entirely restored, with the exception of the placental site, which disappears in about seven weeks. These changes are brought about by encapsulation, by orderly invasion and, finally, by exfoliation by sensible and insensible lochial discharge and fibrolysis. Since the noticeable lochial discharge continues for about two weeks and the regeneration of the placental site is not complete for seven weeks (and only then by a process of exfoliation), it is evident that this material must disappear by some lytic action that causes either its absorption or its insensible discharge. To explain this part of the regeneration Jochman¹⁰ postulated the presence of a proteolytic enzyme in the lochia, and both Irving¹¹ and Beck¹² mentioned a breakdown of protoplasm during the puerperium into simpler substances that are eventually excreted by the kidneys, as evidenced by the fact that nitrogen elimination is doubled during that time.

A possible explanation of the case reported above is that the patient was an elderly primigravida whose past history of short, scanty periods indicated a thin endometrium. It has been shown by Rock¹³ that in

these cases the predecidua — and, it is assumed in pregnancy the decidua as well — is less thick than that usually found, although the cytology denotes the estrogen-progesterone relations to be normal. In other words, there is simply a paucity of normal tissue and no interference with fertility. It is possible that the predecidua and decidua in the case presented were of this type. The amazing rapidity with which the endometrial epithelium covers the denuded menstrual surface of the uterus is known, and the process is believed to start before the patient has stopped flowing. In 1901 Krönig¹⁴ pointed out that, although separation of the placenta and membranes usually occurs in the spongy layer of the decidua, it does not occur as schematically as described in the literature, and he showed that the amount of tissue retained varies greatly, consisting in some places of only a few layers of cells and in others of portions of spongy layer measuring several millimeters in thickness. In 1917, after studying 50 cases in which the uterus had been removed at cesarean section, Williams⁹ concluded that whereas separation generally occurs in the spongy layer, the line of cleavage is extremely irregular, so that in some places a thick layer of decidua and in others only a few layers of cells remain and that in still others the muscularis is practically bare.

In the case presented above it is possible that, at the time the placenta and membranes were expressed after they had begun to separate, there was little decidua left and that what remained was disposed of by rapid autolysis accompanied by a speedy regeneration of the mucosa. After twenty-one days there was probably some bleeding from the placental site in the process of exfoliation, as noted in 60 per

cent of cases by DeLee,¹⁵ with a subsequent resumption of normal menstrual cycles.

* * *

The case of a forty-year-old primigravida delivered by cesarean section four weeks before term is presented. There was complete absence of lochia throughout the puerperium. In other respects, the post-partum course was quite uneventful, and the uterus involuted normally.

A possible explanation for the absence of the lochial discharge is discussed.

The data presented indicate that complete absence of the lochia is compatible with a normal puerperium. Dilatation of the cervix or other operative intervention is contraindicated unless symptoms clearly indicate their necessity.

MEDICAL PROGRESS

THE PHYSIOLOGIC AND CLINICAL SIGNIFICANCE OF PLASMA PROTEINS AND PROTEIN METABOLITES (Concluded)*

JACK METCOFF, M.D.,† AND FREDRICK J. STARE, M.D.‡

BOSTON

CIRCULATING PROTEIN METABOLITES

The circulating plasma proteins represent one phase in the dynamic equilibrium existing between plasma and tissue proteins. Another clinically important phase of protein metabolism in health and disease is associated with the circulating protein catabolites. These nonprotein nitrogenous substances are the resultants of intermediary metabolism of ingested and tissue proteins. The nonprotein nitrogen of the blood—that portion not precipitated by the usual protein precipitants—is a heterogeneous mixture of urea, uric acid, amino acids, creatine, creatinine and a fraction designated as “undetermined nitrogen” that appears to contain polypeptides, various amino acids, adenylic-nucleotide and other components.¹⁰³ The relative concentration ranges of these substances are indicated in Table 7.

Most of the end products of nitrogen metabolism are removed in the urine. An inadequate rate of excretion, whether the result of decreased blood

Changes in blood nonprotein nitrogen may reflect altered concentration of any of its constituents. Most frequently, marked changes are the result of alterations in urea or undetermined nitrogen, or both. Creatine, creatinine, uric acid and amino acid nitrogen concentrations in the blood are relatively small. Fluctuations are usually not attended by marked changes in the nonprotein nitrogen. Increased nitrogen retention, or azotemia, is the resultant of the rate of nitrogen catabolism, hydration, urine volume, nitrogen excretion and mineral metabolism. Azotemia, therefore, is not in itself necessarily indicative of renal damage or permanently impaired renal function. Several conditions that may be associated with altered concentrations of blood nonprotein nitrogenous constituents are listed in Table 8, and detailed discussions of this subject are available in several texts.^{20, 103}

Urea is the chief nitrogenous end product of protein metabolism in mammals. Urea so formed does not enter into further metabolic reactions. The experiments of Bollman, Mann and Magath¹⁰⁴ with hepatectomized dogs demonstrated that the liver was the principal site of urea formation. The bulk of the nitrogen for urea synthesis is derived from the amino nitrogen of the amino acids. Nitrogen from other sources—such as ammonia, absorbed deamination products, amide and other groupings—may be converted into urea. Urea synthesis involves the cyclical participation of several amino acids (arginine, citrulline, ornithine and glutamine), enzymes (arginase), ammonia, carbon dioxide and bicarbonate.¹²⁶⁻¹²⁸ Interrelations between arginine and ornithine in the process of urea formation have been confirmed by isotopic analysis,⁵ but do not completely explain the process of urea formation.¹²⁹ Complete details concerning this fundamental process are as yet unknown.

Urea nitrogen comprises approximately 80 per cent of excreted urinary nitrogen. Urea is a readily diffusible nonelectrolyte and appears in relatively equal proportions throughout the body fluids and tissues.¹⁰³ Clearance of urea from the blood more accurately depicts renal function than blood urea nitrogen concentration. An increase in the urea nitrogen-nonprotein nitrogen ratio may provide a fair indication of decreased urea clearance.¹³⁰ Increased blood urea nitrogen may be the primary result of altered renal structure and function—as

TABLE 7 Relative Concentration Ranges of Blood Nonprotein Nitrogenous Constituents*

CONSTITUENT	PLASMA	BLOOD CORPUSCLES	WHOLE BLOOD
	mg/100 cc	mg/100 cc	mg/100 cc

*Relative ranges are somewhat modified by the method of chemical analysis, metabolic state and preceding dietary pattern of the subject. In some cases the age, sex and physiologic state influence the normal ranges (amino acid nitrogen, creatine, creatinine and uric acid nitrogen).

flow or of reduction in the proportion of protein metabolites removed, is manifested as reduced clearance of these substances from the blood. The ultimate clinical equivalent is retention of nonprotein nitrogen constituents. The significance of these substances in blood rather than in urine is briefly discussed below.

*Tabulated by supplementation of original compilation of Peters and Van Slyke¹⁰² Physiologic variations not tabulated
†Variations in total nonprotein nitrogen of blood not tabulated. Such variation is the summation of contributing variables. Most frequently increased nonprotein nitrogen reflects increased blood urea nitrogen and undetermined nitrogen. It is apparent that in some cases other constituents may be involved. Variations of undetermined nitrogen are not tabulated.

in the nephritides — or may occur in the presence of essentially normal renal structure with either normal or temporarily abnormal function ("prerenal azotemia") — as in gastrointestinal hemorrhage or typhus fever. Pathologic variations occurring in several diseases are indicated in Table 8.

Protein metabolism is essentially the metabolism of the amino acids.¹⁰³ Amino acids absorbed from the intestine — neither deaminated nor synthesized into protein by the liver and supplemented by similar fractions derived from the constant interchange of dietary and tissue protein — constitute the circulating amino acid nitrogen of blood. The amino acid nitrogen concentration of plasma remains quite constant at a level approximating 3 to 6 mg per 100 cc.¹¹⁹ Transient physiologic increases occur following ingestion of a protein meal or parenteral amino acid administration. The liver is the primary site of the deamination of amino acids, and approximately 90 per cent of its functional capacity must be interfered with before deamination is impeded. When urea forming or deaminizing functions of the liver are impaired, the blood amino acid nitrogen increases and the blood urea nitrogen decreases. Urinary amino acid excretion correspondingly increases. With extensive hepatic damage, leucine and tyrosine crystals may be identified in the urine.^{103, 131} Specific amino acid excretion in the urine may occur with rare congenital defects in amino acid metabolism. A partial list of diseases associated with pathologic alterations in amino acid nitrogen is indicated in Table 8. Parenteral administration of amino acid hydrolysates induces a moderate transient increase in blood amino acid and urea nitrogen. Patients with previously elevated serum creatines and associated alterations in utilization or disposal of creatine may evidence a further increase in serum creatine following amino acid administration. The increased creatine is probably derived from the methionine and arginine of the hydrolysate.¹³² Decreases in serum inorganic phosphate attendant to parenteral amino acid administration have been observed.¹³³ A rapid increase of amino acid nitrogen to levels greater than 10 mg per 100 cc on infusion of an amino acid digest may be associated with nausea and vomiting. Glutamic or aspartic acids may be responsible for this phenomenon.¹³³ An increase in plasma amino acid nitrogen (in rats) associated with peripheral circulatory failure and hemorrhagic shock presumably affords an unfavorable prognostic sign.¹³⁴ Elevation of the plasma alpha amino nitrogen levels has been observed in thermal burns.¹³⁵

Creatinine, another component of the nonprotein nitrogen of the blood, is the anhydride of creatine. The formation of creatinine from creatine may proceed without intermediate steps¹³⁶ or may be related to phosphocreatine.¹³⁷ Isotopic technics have indicated that creatine formation is dependent on the formation and methylation of glycocyamine. Choline

or methionine constitutes the principal source of methyl groups.¹³⁸ The nitrogenous constituents of creatine appear to be derived from glycine and arginine.⁵ It is thus apparent that the metabolism of creatine is closely related to choline and at least two amino acids — methionine and arginine. Blood creatine concentration in health is usually constant and clinically insignificant. It may be increased in hyperthyroidism,¹²³ various severe or terminal illnesses and, if initially elevated, following infusion of an enzymatic hydrolysate of casein.¹³² Blood creatinine concentration may vary considerably in disease. Increased concentration may occur in any disease in which marked nonprotein nitrogen retention occurs. Markedly increased blood creatine and creatinine are probably the result of increased endogenous protein catabolism in addition to some degree of impaired excretion. Variation in the rate of excretion of creatine or of creatinine may result from changes in the rate of synthesis of creatine from its precursors, in the ability of tissues to store or to liberate creatine or in the rate or direction of creatine-phosphocreatine reactions.¹³⁹

Uric acid, in man, is the chief end product of exogenous and endogenous nucleoprotein metabolism. In both its synthesis and its excretion, uric acid is closely associated with the amino acids. Glycine, alanine, aspartic, glutamic and pyruvic acids increase uric acid excretion, benzoic and phenylacetic acids depress its excretion. Details of uric acid metabolism remain obscure.¹⁴⁰ The normal concentration of blood uric acid (2 to 6 mg per 100 cc) is little affected by purine-rich foods and is not directly related to the level of nonprotein nitrogen or urea. Abnormal increases of blood uric acid may occur in association with decreased urate elimination by the kidney, primary alterations in nucleoprotein metabolism such as gout, increased endogenous nucleoprotein catabolism as in leukemia or pernicious anemia or excessive nucleoprotein or purine supply associated with these metabolic defects. Destruction of uric acid does not appear to take place in human beings. Like other nonprotein nitrogen catabolites, uric acid is excreted preponderantly in the urine. Urates are freely diffusible, are equally distributed in plasma and glomerular urine and are limitedly concentrated by the tubules. The low tubular concentrating power accounts for the relatively high blood uric acid concentration.¹⁴¹ Uric acid excretion is related to urinary volume and may be increased by the diuresis attendant to continuous infusion of glucose with maintained hyperglycemia.¹⁴² Functional inhibition of urate excretion may explain hyperuricemia. The etiology of tissue urate deposits remains unknown. Hyperuricemia, local trauma, infectious agents, circulatory impairment and primary local tissue changes favor urate precipitation.¹⁴¹ Uricemia associated with several pathologic states is indicated in Table 8.

Ammonia, another of the nitrogenous end products of protein metabolism, results from kidney deamination of alpha-amino groups of amino acids. Dietary ammonia derived from protein digestion products is not a source, and urea is not an intermediate in ammonia formation.⁵ Since the ammonia nitrogen concentration of blood is quite small (less than 0.3 mg per 100 cc) and since conditions that produce a marked increase in urinary ammonia excretion do not appreciably alter blood concentrations,¹⁰³ blood or plasma ammonia nitrogen appears to be of little clinical importance. Urinary ammonia excretion, on the other hand, is of considerable clinical significance, since it represents an attempt to conserve body base.¹⁴³

Undetermined, or residual, nitrogen comprises the final group of nonprotein nitrogenous substances resulting from protein metabolism. Undetermined nitrogen, apparently a cellular component, is said to be composed of hippuric acid, nucleotides and histones.²⁰ Its clinical and metabolic significance is not clear, although a rather large European literature has accumulated. Undetermined nitrogen is usually elevated in disturbances that cause nitrogen retention. In some cases undetermined nitrogen — for practical purposes the difference between urea nitrogen, creatinine nitrogen and the total nonprotein nitrogen — may be of clinical significance. For example, hemorrhage into the gastrointestinal tract is associated with azotemia, which appears to be largely the result of absorption of nitrogenous components from the enteral blood.^{144, 145} Impaired renal function may also be a factor.¹⁴⁶ Continued elevation of the blood urea nitrogen may have prognostic significance.¹⁴⁵ Proportional increases in the undetermined nitrogen fraction may be as great as or greater than increases in urea nitrogen per se and may afford a means of detecting continued gastrointestinal hemorrhage. The azotemia of intestinal obstruction is said to be more closely related to undetermined nitrogen than to urea.¹⁴⁷ In some cases of eclampsia or chronic nephritis with nitrogen retention, undetermined nitrogen may represent the greatest proportional increase in nonprotein nitrogenous substances.²⁰

AMINO ACID AND NITROGEN METABOLISM

The anabolic phase of protein metabolism, that of protein synthesis, was long considered a relatively static process largely restricted in the adult to replacement of the endogenous protein loss of "wear and tear." It was believed by some that body protein was composed of two distinct categories: fundamental structural tissue protein and the more readily utilizable deposit protein of cells and extracellular fluid. It was thought that tissue protein, once formed, remained relatively unchanged until destroyed by metabolic wear and tear. Acute negative nitrogen balance and hypoproteinemia were considered manifestations of deposit protein with-

drawal. The current concept of protein metabolism was evolved from two sources: the suggestion that intracellular protein undergoes continuous change during nitrogen equilibrium at a rate commensurate with nitrogen intake and utilization¹⁴⁸; and observations on plasma protein regeneration and nitrogen balance in the bled, protein-depleted dog subsequent to protein feeding.¹ This theory postulates a continuous dynamic exchange of tissue and plasma proteins.^{1, 2} Direct verification and extension of this concept at the fundamental level of molecular regeneration, involving the constant transfer of specific chemical groups, was obtained by using specific amino acids labeled with isotopes.⁵ Nitrogen in several amino acids was replaced by a heavy atomic analog or isotope, and in some cases, hydrogen of the amino acid carbon chain was also replaced by its heavy isotope, deuterium. By tracing the course of these tagged groups throughout the body, it became evident that both amino nitrogen and the remainder of the amino acid were incorporated in many tissue proteins of the body, including those of the plasma and erythrocyte. It was demonstrated that transfer of entire chemical groups between the various fed and in situ tissue amino acids, as well as their metabolites, constantly occurred. It was inferred that the peptide bonds, which are the chief links binding amino acids into protein structures, are not fixed but rather are rapidly exchanging one constituent group for another. These demonstrated metabolic exchanges, involving both degradation and synthesis, imply enzymatic reactions. Such reactions are not isolated events. Each requires the simultaneous occurrence of others — for example, creatine formation involves groups derived from at least three different amino acids. Two of these amino acids promptly replace their lost fragments from others; other reactions involve cycles, such as urea formation. These metabolic exchanges constitute a fundamental part of the biologic process.⁵

Development of the concept of dynamic equilibrium between tissue and plasma proteins has been attended by observations pertaining to other fundamental roles of certain amino acids in metabolism. The early experimental observations of Osborne and Mendel⁴⁹ provided evidence that two amino acids (lysine and tryptophane) were essential for growth of the rat. This work was extended by the use of diets containing some twenty purified amino acids. When appropriate mixtures were fed to young rats, growth was maintained; in older rats, weight and health were maintained. Omission of individual amino acids indicated that some were indispensable for growth and maintenance and that others were not. By these criteria, a group of ten amino acids were found to be essential for growth of the rat.³ Nitrogen balance studies, utilizing synthetic diets, were extended to adult man and culminated in the observations that only eight amino acids were essential for maintenance of nitrogen

in the nephritides — or may occur in the presence of essentially normal renal structure with either normal or temporarily abnormal function ("prerenal azotemia") — as in gastrointestinal hemorrhage or typhus fever. Pathologic variations occurring in several diseases are indicated in Table 8.

Protein metabolism is essentially the metabolism of the amino acids.¹⁰³ Amino acids absorbed from the intestine — neither deaminated nor synthesized into protein by the liver and supplemented by similar fractions derived from the constant interchange of dietary and tissue protein — constitute the circulating amino acid nitrogen of blood. The amino acid nitrogen concentration of plasma remains quite constant at a level approximating 3 to 6 mg per 100 cc.¹¹⁹ Transient physiologic increases occur following ingestion of a protein meal or parenteral amino acid administration. The liver is the primary site of the deamination of amino acids, and approximately 90 per cent of its functional capacity must be interfered with before deamination is impeded. When urea forming or deaminizing functions of the liver are impaired, the blood amino acid nitrogen increases and the blood urea nitrogen decreases. Urinary amino acid excretion correspondingly increases. With extensive hepatic damage, leucine and tyrosine crystals may be identified in the urine.^{103, 181} Specific amino acid excretion in the urine may occur with rare congenital defects in amino acid metabolism. A partial list of diseases associated with pathologic alterations in amino acid nitrogen is indicated in Table 8. Parenteral administration of amino acid hydrolysates induces a moderate transient increase in blood amino acid and urea nitrogen. Patients with previously elevated serum creatines and associated alterations in utilization or disposal of creatine may evidence a further increase in serum creatine following amino acid administration. The increased creatine is probably derived from the methionine and arginine of the hydrolysate.¹³² Decreases in serum inorganic phosphate attendant to parenteral amino acid administration have been observed.¹³³ A rapid increase of amino acid nitrogen to levels greater than 10 mg per 100 cc on infusion of an amino acid digest may be associated with nausea and vomiting. Glutamic or aspartic acids may be responsible for this phenomenon.¹³³ An increase in plasma amino acid nitrogen (in rats) associated with peripheral circulatory failure and hemorrhagic shock presumably affords an unfavorable prognostic sign.¹²⁴ Elevation of the plasma alpha amino nitrogen levels has been observed in thermal burns.¹³⁵

Creatinine, another component of the nonprotein nitrogen of the blood, is the anhydride of creatine. The formation of creatinine from creatine may proceed without intermediate steps¹³⁶ or may be related to phosphocreatine.¹³⁷ Isotopic technics have indicated that creatine formation is dependent on the formation and methylation of glycocyamine. Choline

or methionine constitutes the principal source of methyl groups.¹³⁸ The nitrogenous constituents of creatine appear to be derived from glycine and arginine.⁵ It is thus apparent that the metabolism of creatine is closely related to choline and at least two amino acids — methionine and arginine. Blood creatine concentration in health is usually constant and clinically insignificant. It may be increased in hyperthyroidism,¹²³ various severe or terminal illnesses and, if initially elevated, following infusion of an enzymatic hydrolysate of casein.¹²² Blood creatinine concentration may vary considerably in disease. Increased concentration may occur in any disease in which marked nonprotein nitrogen retention occurs. Markedly increased blood creatine and creatinine are probably the result of increased endogenous protein catabolism in addition to some degree of impaired excretion. Variation in the rate of excretion of creatine or of creatinine may result from changes in the rate of synthesis of creatine from its precursors, in the ability of tissues to store or to liberate creatine or in the rate or direction of creatine-phosphocreatine reactions.¹³⁹

Uric acid, in man, is the chief end product of exogenous and endogenous nucleoprotein metabolism. In both its synthesis and its excretion, uric acid is closely associated with the amino acids. Glycine, alanine, aspartic, glutamic and pyruvic acids increase uric acid excretion, benzoic and phenylacetic acids depress its excretion. Details of uric acid metabolism remain obscure.¹⁴⁰ The normal concentration of blood uric acid (2 to 6 mg per 100 cc) is little affected by purine-rich foods and is not directly related to the level of nonprotein nitrogen or urea. Abnormal increases of blood uric acid may occur in association with decreased urate elimination by the kidney, primary alterations in nucleoprotein metabolism such as gout, increased endogenous nucleoprotein catabolism as in leukemia or pernicious anemia or excessive nucleoprotein or purine supply associated with these metabolic defects. Destruction of uric acid does not appear to take place in human beings. Like other nonprotein nitrogen catabolites, uric acid is excreted preponderantly in the urine. Urates are freely diffusible, are equally distributed in plasma and glomerular urine and are limitedly concentrated by the tubules. The low tubular concentrating power accounts for the relatively high blood uric acid concentration.¹⁴¹ Uric acid excretion is related to urinary volume and may be increased by the diuresis attendant to continuous infusion of glucose with maintained hyperglycemia.¹⁴² Functional inhibition of urate excretion may explain hyperuricemia. The etiology of tissue urate deposits remains unknown. Hyperuricemia, local trauma, infectious agents, circulatory impairment and primary local tissue changes favor urate precipitation.¹⁴¹ Uricemia associated with several pathologic states is indicated in Table 8.

The continuous formation of plasma proteins is dependent on the supply and adequacy of amino acids and the integrity of their synthesis. Information pertaining to the amino acid composition of

and that associated with antibody formation and immune response may involve different amino acids in varying degrees. On the other hand, amino acid contributions derived from injection of whole blood,

TABLE 10 *Metabolic Implications of the Essential Amino Acids*

AMINO ACID	GENERAL CLASSIFICATION	HUMAN PLASMA COMPOSITION*		KNOWN METABOLIC FUNCTIONS†	CLINICAL SIGNIFICANCE‡
		ALBUMIN %	GLOBULIN %		
Leucine	Mono-amino	11.9	8.9-9.3	May contribute to acetone-body formation in rat ¹⁶⁵ by conversion to trihydroxybutyric acid; carbon chain indispensable	Presumably ketogenic
Isoleucine	-	2.0 ¹⁶⁵	?	May contribute to either acetone-body formation or glycogen deposition under appropriate conditions ¹⁶⁶	Possible limiting factor in human albumin ¹⁶⁷ and plasma therapy
Valine	-	4.1 ¹⁶⁵	?	Glycogenic; decreases experimental ketosis in rats	Deprivation in rats leads to hyperesthesia and severe unco-ordination ¹⁶⁸
Lysine	Di-basic	5.8	6.7	Unlike other amino acids does not readily undergo reamination; therefore presumably represents isolated example of amino acid not reversibly involved in the nitrogen shift; unlike other essential amino acids cannot be replaced by any of its deamination products in metabolism ⁵	Forms cadaverine; a ptomaine on decarboxylation; this is probably of little clinical significance ¹⁷⁰
Arginine	-	6.15	4.8-5.6	Forms ornithine and urea — both concerned in mechanism of urea formation ¹⁷² ; one of precursors of creatine ¹⁷⁶ and probably glutamic acid	Deficiency may impede spermatogenesis ¹⁷¹
Histidine	-	3.5	2.5	Splitting of carbon chain catalyzed by enzymes may yield glutamic acid or histamine or both	Constituent of normal pregnancy urine but not pathognomonic of pregnancy; its elaboration not essential for maintenance of positive nitrogen balance in man (hence dispensable)
Threonine	Hydroxy	5.03	7.3-8.3	May be glycogenic; appears to decrease experimental ketonuria in rat.	
Tryptophane	Aromatic heterocyclic	0.19	2.1-2.9	Metabolic precursor of kynurenic acid and indican which may be normal urinary constituents; and possibly one of precursors of urinary pigment urochrome; intestinal bacterial flora produce indole and skatole from this amino acid	Odor of feces; deficiency leads to cataract formation in the rat ¹⁷² ; human albumin deficient in tryptophane ¹⁷³
Phenylalanine	Aromatic	7.5 ¹⁶⁵	5.9 ¹⁶⁵	May be converted to tyrosine or pursue another metabolic path to phenylpyruvic acid; when converted to tyrosine becomes implicated in synthesis of melanin (skin pigment); tyrosine (diiodotyrosine) and adrenaline; defect in conversion of phenylalanine to tyrosine may be associated with ascorbic acid metabolism (vitamin C) ¹⁷⁴ particularly in premature infants	Albinism may result from enzymic failure of melanin production; alcaptonuria results from incomplete metabolism of phenylalanine and tyrosine and is result of homogentisic acid excretion in urine; oligophrenic phenylpyruvica probably represents failure of conversion of phenylalanine to tyrosine ¹⁷⁴ and is associated with mental deficiency and neurologic stigmas
Methionine	Sulfur-containing	1.28	1.1-1.5	Methionine sulfur may be converted to cystine sulfur ⁵ by relation to cystine; may be implicated in glutathione formation which is important respiratory enzyme; may be precursor of taurocholic bile component by contributing methyl groups; is associated with <i>in vivo</i> synthesis of choline and creatine ⁵ ; if converted to cystine or by contributing methyl groups may be involved in certain detoxication phenomena	Insulin contains cystine; methyl group deficiency may result in fatty livers and abnormal creatine metabolism; deficiency is associated with susceptibility of rat to virus of infectious hepatitis ¹⁷⁵ ; bromobenzene detoxication; cystinuria is congenital defect of cystine metabolism; is involved in conjugation of benzoic to hippuric acid.

*Data pertaining to the amino acid composition of protein is limited by the inadequacy of present analytic methods. The major part of the plasma protein composition data is derived from Brand, Kassel, and Saidel.⁸² The figures for globulin represent values determined for purified gamma globulin and fraction III-2 (beta) globulin.

†All amino acids undergo deamination yielding amino and other groups to the body metabolic pool.

‡Specific clinical significance except that pertaining to maintenance of nitrogen balance and certain congenital defects is not well known at present.

plasma protein, therefore, has clinical importance. The protein depletion and requirement attendant to burns, that occurring in response to various diseases, such as malnutrition, nephrosis or hepatitis,

plasma or plasma fractions may vary. The partial amino acid composition of the major plasma protein components has been tentatively stated.⁸² Albumin contains at least five and probably six essential

equilibrium during the periods of observation^{3, 4} (Table 9)

Nitrogen balance describes the relation between nitrogen intake and output. Positive balance means that less nitrogen is lost from the body than is taken in — nitrogen is being stored. Negative nitrogen balance is exactly the opposite. A positive nitrogen balance represents a desirable state of retention and utilization of protein. The metabolism of amino

*Classification of the usual 22 amino acids as essential or nonessential has resulted largely from the work of Rose³ and his colleagues. In rats an essential amino acid is defined as "one which cannot be synthesized by the animal organism out of the materials ordinarily available, at a speed commensurate with the demands for normal growth."

In man nitrogen balance studies in young adults have been the principal technique used to examine the essentiality of amino acids.⁴

†Arginine can be slowly synthesized by the rat, but not at a sufficiently rapid rate to maintain reasonably good growth.

acids and proteins is partially reflected in the nitrogen balance of the individual. Normal growth¹⁵⁰ and maintenance¹⁵¹ are associated with positive nitrogen balances. Various pathologic states are associated with a loss of nitrogen in their acute or chronic phases, or both.^{152, 153} The negative nitrogen balances observed in these conditions are rather difficult to explain. Apparently, negative balance is not the direct result of diminished protein absorption, disuse atrophy, local toxic tissue destruction, accelerated energy expenditure or heat production or the degree of febrile reaction. Protein metabolic pathways may be distorted, and protein synthesis diminished. The duration and degree of retarded protein synthesis presumably varies inversely with the previous nutritional state and directly with the severity of the disease or injury. It may represent a reparative rather than a primarily destructive process.¹⁵³ Nitrogen lost in such conditions is thought to be derived primarily from tissue protein. This nitrogen loss may be influenced by endocrinologic interrelations. The effect of anterior pituitary growth hormone on nitrogen metabolism in the growing child is well known. Androgens, such as testosterone propionate, initiate nitrogen retention in normal men and women,¹⁵⁴ as well as in eunuchoidal males,¹⁵⁵ and have been observed to induce nitrogen retention in a female patient with Cushing's syndrome.¹⁵⁶ Such hormone administration appears to exert a somatotrophic effect on protein deposition, being associated with decreased urinary excretion of phosphorus, potassium and creatine. Despite quantitative nitrogen retention associated with the

administration of chorionic gonadotropin, testosterone propionate or methyl testosterone, these hormones apparently exert little effect on either the total circulating plasma protein or the concentration of albumin or globulin.¹⁵⁷ Relative hypoproteinemia occurring shortly after androgen administration suggests either accelerated formation of tissue protein derived from plasma protein or preferential synthesis of the tissue protein.¹⁵⁸

The relation of adrenal steroids to nitrogen metabolism is not clear. In general, the metabolic effect attending administration of that group of adrenocortical steroids having an oxygen in the C11 position may eventuate in negative nitrogen balance. It has been suggested that the negative balance represents heightened gluconeogenesis, a manifestation of increased protein catabolism,¹⁵⁹ or conversely, lowered protein synthesis, a manifestation of decreased protein anabolism.¹⁶⁰ It has also been suggested that adrenocortical hormone directly influences the conversion of tissue proteins to amino acids¹⁶¹ and enhances the rate of amino acid deamination¹⁶² and that the adrenal cortex elaborates a nitrogen-sparing factor. Impaired production of this factor may be responsible for the protracted biologic and metabolic abnormality following acute injury,¹⁶⁰ characterized as the so-called "alarm reaction" of Selye.¹⁶³ The negative nitrogen balance associated with impaired synthesis or protein depletion, or both, may eventually condition the occurrence of a clinical protein-deficiency state. Provision of a high protein intake during both the immediate catabolic and later convalescent phase following infection or injury minimizes this conditioned malnutrition.

The amino acids are usually obtained from dietary sources. Peptic, tryptic and enteric digestion of protein provides assimilable amino acids that are largely absorbed unchanged in the small intestine but may enter the circulation via thoracic-duct lymph. Absorbed amino acids are readily taken up by the tissues, particularly the liver.¹⁶⁴ Some amino acids serve as precursors or constituents of biologic substances, such as vitamins, co-enzymes, hormones and various detoxication products. Some are converted into tissue proteins. Others may be utilized for energy or contribute directly to the various non-protein nitrogen moieties. Some of the metabolic implications of the essential amino acids are given in Table 10.

The metabolism of the amino acids involves deamination (removal of the alpha-amino group), amination (the reverse of this procedure) and transamination (amination without participation of ammonia).¹⁷⁶ The energy derived from these metabolic reactions is reported to account for the elevated basal metabolic rate, or the so-called "specific dynamic action," following ingestion or infusion of proteins or amino acids.¹⁷⁷

CASE 33021

PRESENTATION OF CASE

A twenty-seven-year-old, single, unemployed man entered the hospital because of chronic diarrhea and weight loss

Five years before admission the patient had suddenly developed lower abdominal cramps and profuse watery diarrhea He was admitted to a hospital, where a diagnosis of chronic ulcerative colitis was confirmed by x-ray and sigmoidoscopic examinations Repeated search for parasites in the stools was negative, as were blood cultures and serologic tests After four weeks he was discharged essentially unimproved, having lost 30 pounds He remained at home on restricted activity, with persistent, nonbloody diarrhea (five or six movements daily) A year later an exacerbation sent him to

another hospital for three months By the time of discharge the diarrhea had subsided, and he had regained the weight lost He then worked as a taxi driver for six weeks before another exacerbation sent him home, where he remained a chronic and neglected invalid until a month before admission. At that time, with the onset of an upper respiratory infection, the diarrhea became worse, and the patient's general condition deteriorated rapidly Anorexia, edema, weakness and severe perianal inflammation developed The weight fell from 125 to 85 pounds

Physical examination disclosed a pale and emaciated patient with a moderate pitting edema up to the axilla He lay incontinent in bed, discharging semisolid stools frequently The skin was dry, shiny, tender and red over both femoral trochanters Severe inflammation with multiple draining abscesses surrounded the anus The tongue was abnormally reddened, with irregular patches of denudation of the epithelium The prepuce was edematous There was dullness over the right lung base, and the breath sounds were diminished The abdomen was tense but not tender The area of liver dullness extended 2 cm below the costal margin

The temperature was 98°F, the pulse 92, and the respirations 22 The blood pressure was 90 systolic, 60 diastolic

Examination of the blood revealed a red-cell count of 3,700,000, with a hemoglobin of 8 gm per 100 cc, and a white-cell count of 8500, with 66 per

amino acids — lysine, methionine, tryptophane, threonine and leucine and probably arginine — but is relatively low in tryptophane and isoleucine^{167, 178} Gamma globulin similarly contains at least these five essential amino acids with relatively large numbers of hydroxy-amino groups affording easily labile hydrogen bonds, beta globulin and fibrinogen include at least four of the essential amino acids, apparently lacking lysine

Many amino acids are intimately concerned with the metabolism of carbohydrate. There is some evidence that much of the carbohydrate formed after the administration of glycogenic amino acids such as glycine does not originate by direct conversion of the amino acid¹⁷⁹ but may depend on enzymatic conversion of some intermediary metabolite¹⁷⁶ Many of the vitamin B components involved in carbohydrate metabolism function as prosthetic groups of enzymes. Undoubtedly, specific amino acid complexes are necessary for the formation of the appropriate enzyme system

The relation of specific amino acids to some mechanisms of immunity is of considerable interest. It is thought that simple amino acids, as such, are not of primary significance in this regard. They are, however, indirectly involved as structural units in more complex proteins. According to Pauling's¹⁸⁰ theory of antibody formation, reactive antigen having a specific pattern penetrates to the sites of globulin formation and stimulates synthesis of specifically modified antibody globulin. The antibody globulin chain is modified, during synthesis, by coiling about the reactive antigen groups in such fashion as to template their configuration by surface approximation — thus achieving specificity¹⁸⁰. The spatial modification of the newly synthesized antibody globulin may owe its lability to the large number of easily converted hydrogen bonds contributed by hydroxy-amino acids, such as tyrosine, serine and threonine¹⁸¹. Threonine is an indispensable amino acid and must be supplied preformed in the diet. Tyrosine may be derived from phenylalanine, another essential amino acid. These amino acids are components of gamma globulin. Analyses of large quantities of several specific antigen-antibody precipitates have indicated an amino acid composition similar to that of typical serum globulin¹⁸². Application of isotopic analytic methods has demonstrated that protein antibody in actively immunized animals takes up dietary nitrogen in a manner similar to that of plasma globulin and other tissue proteins^{6, 7}. The available evidence, therefore, indicates that specific protein antibody synthesis is merely one phase of general protein synthesis and is at least partially dependent on adequate amino acid supply and metabolism.

SUMMARY

The application of newer experimental technics to problems of protein structure and function has

abetted clinical understanding of plasma protein significance. This paper attempts to correlate some of the recent data derived from physiologic, biochemical, physicochemical, nutritional, immunologic and clinical investigations in terms of their clinical implications.

CASE 33021

PRESENTATION OF CASE

A twenty-seven-year-old, single, unemployed man entered the hospital because of chronic diarrhea and weight loss.

Five years before admission the patient had suddenly developed lower abdominal cramps and profuse watery diarrhea. He was admitted to a hospital, where a diagnosis of chronic ulcerative colitis was confirmed by x-ray and sigmoidoscopic examinations. Repeated search for parasites in the stools was negative, as were blood cultures and serologic tests. After four weeks he was discharged essentially unimproved, having lost 30 pounds. He remained at home on restricted activity, with persistent, nonbloody diarrhea (five or six movements daily). A year later an exacerbation sent him to

another hospital for three months. By the time of discharge the diarrhea had subsided, and he had regained the weight lost. He then worked as a taxi driver for six weeks before another exacerbation sent him home, where he remained a chronic and neglected invalid until a month before admission. At that time, with the onset of an upper respiratory infection, the diarrhea became worse, and the patient's general condition deteriorated rapidly. Anorexia, edema, weakness and severe perianal inflammation developed. The weight fell from 125 to 85 pounds.

Physical examination disclosed a pale and emaciated patient with a moderate pitting edema up to the axilla. He lay incontinent in bed, discharging semisolid stools frequently. The skin was dry, shiny, tender and red over both femoral trochanters. Severe inflammation with multiple draining abscesses surrounded the anus. The tongue was abnormally reddened, with irregular patches of denudation of the epithelium. The prepuce was edematous. There was dullness over the right lung base, and the breath sounds were diminished. The abdomen was tense but not tender. The area of liver dullness extended 2 cm below the costal margin.

The temperature was 98°F, the pulse 92, and the respirations 22. The blood pressure was 90 systolic, 60 diastolic.

Examination of the blood revealed a red-cell count of 3,700,000, with a hemoglobin of 8 gm per 100 cc, and a white-cell count of 8500, with 66 per

cent neutrophils. The urine had a specific gravity of 1.026, with occasional white cells in the sediment, and examination was negative for albumin, sugar, red cells and casts. Guaiac tests on the stools were strongly positive. The total serum protein was 3.67 gm, and the nonprotein nitrogen 22 mg per 100 cc, the sodium was 140.3 milliequiv, and the chloride 102 milliequiv per liter. An x-ray film of the chest showed a small amount of fluid on each side, with a few linear areas of density in the lingula of the left upper lobe.

In the hospital the patient's condition was consistently unsatisfactory. On the fourth hospital day massive swelling of the scrotum, penis and legs had developed, along with generalized itching and a pink papular rash on the abdomen and legs, the administration of 3 gm of sulfadiazine daily was begun. A single whole-blood transfusion was given each day for five days, and the hemoglobin increased to 12 gm per 100 cc. After the fifth transfusion the patient suffered a chill, and the temperature rose to 100.8°F. Within the next twenty-four hours the urinary output fell from a former level of 1750 cc to 750 cc, it remained low for several days, gradually returning to a level of 2250 cc by the fourteenth day. The urine gave a + test for albumin on the fourth day and a ++++ test on the ninth. Thereafter, the test was +++ to ++++, the reaction was acid, and the specific gravity was between 1.004 and 1.014. The sediment on numerous occasions had 5 or 6 white cells, occasional red cells and 0 to many hyaline casts per high-power field.

Doses of 200 cc of human serum albumin were given daily for nearly two weeks. The total protein rose from 3.67 to 4.42 gm per 100 cc, with an albumin-globulin ratio of 1.56. Other treatment consisted of vitamins, 10 per cent Amigen, dextrose in water and courses of sulfapyridine and, later, penicillin. The diarrhea persisted. For many days the patient was markedly edematous despite the daily output of 2000 to 2500 cc of urine, which contained from 23 to 45 gm of protein on numerous determinations. He had satisfactory diuresis only after the administration of acacia, a total of 150 gm having been given. The temperature ranged between 99 and 101°F.

X-ray examinations of the chest continued to show small to moderate amounts of fluid, with occasional areas of density and haziness suggesting consolidation or multiple infarcts. Toward the end of the second hospital week the abdomen became diffusely tender and remained so for several days.

During the first month the serum protein level was usually about 4 gm, and the nonprotein nitrogen 20 to 24 mg per 100 cc. A phenolsulfonephthalein test on the twenty-fifth day showed 25 per cent excretion of the dye in thirty minutes and 60 per cent in two hours. A Congo-red test at about that time showed 33 per cent retention of the dye in the serum.

Mercupurin was given after the supply of serum albumin ran out. The edema gradually diminished and the temperature approached normal, but the patient remained extremely ill. The sinuses about the anus continued to drain. On the forty-fifth hospital day an ileostomy was performed. Post-operatively intractable small-bowel distention developed. The urine output fell to 200 cc over a seven-day period, and the nonprotein nitrogen rose to 150 mg per 100 cc. The insertion of a Miller-Abbott tube failed to improve the distention. The chloride fell to 76 milliequiv per liter. Terminally there was anuria for thirty-six hours. Hyperpnea and involuntary movements developed, and death occurred on the fifty-fourth hospital day.

DIFFERENTIAL DIAGNOSIS

DR MARIAN W. ROPES: In this patient there were surely two major sites of disease—the gastrointestinal tract and the genitourinary tract. As I see it, the problem is to decide the nature of the two diseases, whether they were interrelated and, if so, in what manner. So far as the gastrointestinal disease is concerned, the history, in general, is consistent with that of chronic idiopathic ulcerative colitis. Unfortunately we are not told anything about the results of proctoscopic or x-ray studies, but we are told that they were consistent with this disease at least during the first attack. It would be of interest to know if these studies were repeated during the second attack and, if so, what the findings were.

DR HAROLD E. ELRICK: Barium-enema and proctoscopic examinations were not done.

DR ROPES: I assume that the findings in the first attack corroborated the diagnosis and that the findings in the terminal attack were similar. There are some unusual features, however. The degree of perianal inflammation with many draining abscesses is unusual, this is not inconsistent with the diagnosis, however, and does not make it necessary for us to consider seriously other possible causes of ulcerative colitis, such as tuberculosis. The degree of edema seems definitely more than one would expect in such a patient with ulcerative colitis, particularly since the edema apparently persisted and possibly increased, although it is difficult to be sure of that, since the serum protein rose to 4.5 gm per 100 cc. If the edema had been on a purely nutritional basis it would have been unusual for it to fail to respond to the administration of albumin, with its resulting elevation of the serum protein, and subsequently to respond to acacia. In addition, the pulmonary changes were not characteristic.

May we see the x-ray films?

DR TRACY B. MALLORY: The X-ray Department sent the report over that there was no point in showing the films, which add nothing to what is given in the record.

DR ROPES The fluid in the pleural cavities is consistent with a generalized anasarca. The small areas of consolidation varying from time to time are difficult to interpret, I think that they were not specifically related to the underlying gastrointestinal or genitourinary disease. The changes in the skin and tongue were in general consistent with the nutritional disturbance. That is not true of the rash, and I find no explanation for the itching and rash, which were probably associated, other than the possibility of some medication that we do not know about. Clubbing of the fingers, I judge, was not recent. I should have thought that it would have been seen after five years of ulcerative colitis.

DR ELRICK It was present.

DR ROPES Apparently, there were no joint symptoms, which might have been expected, since joint involvement is not too rare in ulcerative colitis. The abdominal tenderness in the second week is consistent with the degree of tenderness seen in uncomplicated ulcerative colitis, but the suddenness of onset suggests the possibility of a small perforation, which I consider unlikely, however. Similarly, the ileus, with the small-bowel obstruction and distention that occurred following operation, could have been secondary to the disease itself but suggests the possibility of superimposed peritonitis. In general, therefore, the gastrointestinal involvement is consistent with chronic ulcerative colitis — but not the genitourinary involvement.

Several possibilities should be considered regarding the genitourinary difficulties. As I have said, the degree of edema was out of proportion to what one would expect in a patient with ulcerative colitis at that stage. It suggests a nephrotic state. There is little evidence that this could have been the nephrotic state of chronic nephritis, although it is impossible to rule out nephritis. The onset of the acute illness following a respiratory infection and the sudden downhill course suggest that diagnosis, but the findings are somewhat against it. On the other hand, the urinary findings, with the high albumin in the absence of cells and the presence of only a few or a moderate number of casts, the nephrotic picture, the low nonprotein nitrogen until the terminal stage and the relatively good phenol-sulfonephthalein excretion are typical of amyloid disease of the kidney.

Another possibility to be considered is whether or not sulfonamide treatment or transfusion reaction caused any of the renal damage in this patient, as suggested by the few signs of renal involvement at the time of admission and the marked changes after sulfonamide treatment had been started and after the transfusion reaction. On the other hand, such marked changes without elevation of the nonprotein nitrogen lasting for a long period are unusual in kidney damage due to either of these factors alone. Therefore, I think that amyloid involvement of the kidney is the most probable explanation of the

renal disease. If so, it is interesting, because such involvement in ulcerative colitis is, I think, extremely rare. I know of only one case in the literature — that reported by Moschowitz,* ten years ago. The serum globulin, which is frequently high in the diseases to which amyloid is secondary, was definitely low in this patient — below 2 gm per 100 cc. The liver enlargement is consistent with amyloid disease but is not greater than what one would expect with ulcerative colitis of this severity. If amyloid disease caused the renal involvement, the question arises whether sulfonamide treatment or a transfusion reaction hastened the renal failure. I think that this is impossible to answer clinically. I have been impressed, however, with the course of two patients with amyloid disease of the kidney who died here fairly recently. Both went rapidly into renal failure with marked urinary changes, and in both sulfonamides or penicillin had been given before the changes occurred. I have no idea whether or not the sulfonamide treatment or transfusion reaction was related to the renal failure in this patient.

If this patient had amyloidosis secondary to ulcerative colitis, it is of interest that amyloidosis is not a rare complication of rheumatoid arthritis and that rheumatoid arthritis is often associated with ulcerative colitis. In the hospital at the present time we have a woman with probable rheumatoid arthritis, acute ulcerative colitis and amyloid disease.

In putting this picture together, therefore, I shall conclude that this patient had chronic idiopathic ulcerative colitis, with secondary amyloid disease involving at least the kidneys. Whether the liver was also involved, I do not know, although it is probable that it was. I do not know whether the sulfonamide treatment or transfusion reaction further damaged a kidney in which amyloid disease was already present.

DR JOSEPH C AUB Would Dr Ropes like to suggest that this man had amyloid disease of the small intestine?

DR ROPES We have had a great deal of discussion regarding whether or not amyloid disease gives active clinical disease of the gastrointestinal tract. There is no question that amyloid can be deposited in the gastrointestinal tract. The clinical symptoms arising from this amyloid involvement are apparently rare. We have a patient in the hospital with amyloidosis and small polypoid masses in the lower gastrointestinal tract, one of which has been biopsied. I do not know the result.

DR AUB I have seen amyloid disease with involvement of the whole small intestine.

DR ROPES With symptoms?

DR AUB I cannot remember.

DR CHARLES H BURNETT We were perplexed in the same way about the renal situation and the

*Moschowitz E. Clinical aspects of amyloidosis. *Ann Int Med* 10: 3-85 1936.

cent neutrophils. The urine had a specific gravity of 1.026, with occasional white cells in the sediment, and examination was negative for albumin, sugar, red cells and casts. Guaiac tests on the stools were strongly positive. The total serum protein was 3.67 gm, and the nonprotein nitrogen 22 mg per 100 cc, the sodium was 140.3 milliequiv, and the chloride 102 milliequiv per liter. An x-ray film of the chest showed a small amount of fluid on each side, with a few linear areas of density in the lingula of the left upper lobe.

In the hospital the patient's condition was consistently unsatisfactory. On the fourth hospital day massive swelling of the scrotum, penis and legs had developed, along with generalized itching and a pink papular rash on the abdomen and legs, the administration of 3 gm of sulfadiazine daily was begun. A single whole-blood transfusion was given each day for five days, and the hemoglobin increased to 12 gm per 100 cc. After the fifth transfusion the patient suffered a chill, and the temperature rose to 100.8°F. Within the next twenty-four hours the urinary output fell from a former level of 1750 cc to 750 cc, it remained low for several days, gradually returning to a level of 2250 cc by the fourteenth day. The urine gave a + test for albumin on the fourth day and a ++++ test on the ninth. Thereafter, the test was +++ to ++++, the reaction was acid, and the specific gravity was between 1.004 and 1.014. The sediment on numerous occasions had 5 or 6 white cells, occasional red cells and 0 to many hyaline casts per high-power field.

Doses of 200 cc of human serum albumin were given daily for nearly two weeks. The total protein rose from 3.67 to 4.42 gm per 100 cc, with an albumin-globulin ratio of 1.56. Other treatment consisted of vitamins, 10 per cent Amigen, dextrose in water and courses of sulfapyridine and, later, penicillin. The diarrhea persisted. For many days the patient was markedly edematous despite the daily output of 2000 to 2500 cc of urine, which contained from 23 to 45 gm of protein on numerous determinations. He had satisfactory diuresis only after the administration of acacia, a total of 150 gm having been given. The temperature ranged between 99 and 101°F.

X-ray examinations of the chest continued to show small to moderate amounts of fluid, with occasional areas of density and haziness suggesting consolidation or multiple infarcts. Toward the end of the second hospital week the abdomen became diffusely tender and remained so for several days.

During the first month the serum protein level was usually about 4 gm, and the nonprotein nitrogen 20 to 24 mg per 100 cc. A phenolsulfonephthalein test on the twenty-fifth day showed 25 per cent excretion of the dye in thirty minutes and 60 per cent in two hours. A Congo-red test at about that time showed 33 per cent retention of the dye in the serum.

Mercupurin was given after the supply of serum albumin ran out. The edema gradually diminished and the temperature approached normal, but the patient remained extremely ill. The sinuses about the anus continued to drain. On the forty-fifth hospital day an ileostomy was performed. Postoperatively intractable small-bowel distention developed. The urine output fell to 200 cc over a seven-day period, and the nonprotein nitrogen rose to 150 mg per 100 cc. The insertion of a Miller Abbott tube failed to improve the distention. The chloride fell to 76 milliequiv per liter. Terminally there was anuria for thirty-six hours. Hyperpnea and involuntary movements developed, and death occurred on the fifty-fourth hospital day.

DIFFERENTIAL DIAGNOSIS

DR MARIAN W. ROPES: In this patient there were surely two major sites of disease—the gastrointestinal tract and the genitourinary tract. As I see it, the problem is to decide the nature of the two diseases, whether they were interrelated and, if so, in what manner. So far as the gastrointestinal disease is concerned, the history, in general, is consistent with that of chronic idiopathic ulcerative colitis. Unfortunately we are not told anything about the results of proctoscopic or x-ray studies, but we are told that they were consistent with this disease at least during the first attack. It would be of interest to know if these studies were repeated during the second attack and, if so, what the findings were.

DR HAROLD E. ELRICK: Barium-enema and proctoscopic examinations were not done.

DR ROPES: I assume that the findings in the first attack corroborated the diagnosis and that the findings in the terminal attack were similar. There are some unusual features, however. The degree of perianal inflammation with many draining abscesses is unusual, this is not inconsistent with the diagnosis, however, and does not make it necessary for us to consider seriously other possible causes of ulcerative colitis, such as tuberculosis. The degree of edema seems definitely more than one would expect in such a patient with ulcerative colitis, particularly since the edema apparently persisted and possibly increased, although it is difficult to be sure of that, since the serum protein rose to 4.5 gm per 100 cc. If the edema had been on a purely nutritional basis it would have been unusual for it to fail to respond to the administration of albumin, with its resulting elevation of the serum protein, and subsequently to respond to acacia. In addition, the pulmonary changes were not characteristic.

May we see the x-ray films?

DR TRACY B. MALLORY: The X-ray Department sent the report over that there was no point in showing the films, which add nothing to what is given in the record.

ak, noted palpitation and found it difficult to breathe. There was a sense of substernal oppression but no pain. A physician found a blood pressure of 230 systolic, 140 diastolic, albuminuria and glycosuria. The face was swollen. The patient remained in bed for twelve days with orthopnea and severe generalized abdominal pain, he also had a severe frontal headache, dizziness and black spots before the eyes. Vague pains and numbness on the dorsal surfaces of the feet and in the right shoulder were observed at the same time. These symptoms, which persisted and increased during the succeeding months, constituted the chief complaint on admission. Four and a half months before admission the patient was admitted to another hospital. Albuminuria was marked, the fasting blood sugar was 70 mg per 100 cc. The nonprotein nitrogen was normal, and an intravenous pyelogram showed 34 per cent excretion of the dye in one hour. Red and white cells were found in the urinary sediment. The patient was discharged in ten days still not improved. There were persistent hematuria and a weight loss of 14 pounds. He was taking 14 units of protamine zinc insulin daily. Two weeks later he felt sufficiently improved to go back to work. Blurring of vision and pain in the feet and shoulders persisted. Two and a half months later follow-up examination at the same hospital showed the blood pressure to be 194 systolic, 78 diastolic, and the nonprotein nitrogen to be 74 mg per 100 cc. Thereafter he was followed in the Out Patient Department of this hospital, where the blood sugar levels were found to be 135, 149 and 258 mg per 100 cc on different occasions. There were a moderate anemia and a moderate leukocytosis, as well as a carbon dioxide combining power between 23.5 and 25.8 milliequiv per liter.

Physical examination on entry showed an apical systolic murmur, the aortic second sound was louder than the pulmonic. The blood pressure was 172 systolic, 98 diastolic. There were small hemorrhages in both fundi, and a few whitish exudates were seen. The lungs were normal. Pulsations were felt in all the main arteries of the lower extremities, and oscillographic abnormalities were minimal. Neurologic examination showed only a slight decrease in vibration and position sense in the lower extremities. The knee and ankle jerks were hyperactive but equal.

Examination of the blood revealed a red-cell count of 3,300,000, with a hemoglobin of 70 per cent. The urine gave a ++ test for albumin. The urinary sediment contained occasional white cells and 4 or 5 red cells per high-power field, with rare hyaline and finely granular casts. Cultures of the urine showed no growth. The phenolsulfonephthalein test showed 17 per cent excretion of the dye in one hour and 24 per cent excretion in two hours. The nonprotein nitrogen was 66 mg, and the fasting blood sugar 135 mg per 100 cc. The urine sugar reactions were consistently green. Plain films of the abdomen

showed the kidney outlines to be indistinct, the left kidney appeared normal, and the right was not definitely visible. On an x-ray film of the chest the heart did not appear definitely enlarged. Films of the feet showed slight calcification of the dorsalis pedis arteries. An electrocardiogram taken shortly after admission demonstrated slightly sagging ST segments in Leads 1, 2 and 3, a depressed ST₄, and a sharply diphasic T₄. The rhythm was normal.

Treatment consisted of warm foot baths, massage and exercises. The pain and numbness in the lower extremities rapidly disappeared. On the fourth and sixth days the urine contained many red cells, but there was no other outward incident in the twelve-day hospital stay.

Final admission (six years later) After discharge the patient was followed in the diabetic clinic, where the blood sugar was normal and glycosuria was absent. He was taking 16 units of protamine zinc insulin daily and was following his diet. On the last visit to the clinic, five years before admission, the nonprotein nitrogen was 38 mg per 100 cc. The patient was fairly well until a year before admission, when he began to notice severe progressive weakness, dyspnea and failing vision. He was given digitalis by a physician, but the symptoms continued. He also suffered from urinary difficulty with nocturia and frequency. For several weeks before admission he had been confined to bed. Five days before admission he developed an epistaxis, which persisted and brought him to the Emergency Ward.

Physical examination showed an emaciated, pale and weak man who was bleeding profusely from the right nostril and gagging from blood clots in the nasopharynx. During the examination he vomited 60 cc of clotted blood. The pupils were small, but reacted to light and accommodation. The neck veins were distended, and the heart enlarged, extending 10 cm to the left of the midsternal line in the sixth interspace. There were no murmurs. There were rales at the bases of both lungs. The liver edge was palpable 4 cm below the costal margin. The bladder was felt 4 cm above the symphysis. There was thickening of the epididymis. The prostate was symmetrically enlarged and indurated. There was moderate pitting edema of the ankles and legs.

The temperature was 98.8°F, the pulse 105, and the respirations 20. The blood pressure was 160 systolic, 90 diastolic.

Examination of the blood revealed a red-cell count of 2,050,000, with a hemoglobin of 7 gm, and a white-cell count of 12,300, with 90 per cent neutrophils. The specific gravity of the urine was 1.004. The sugar reaction was green. On admission there was no albumin, but on the next day there was a ++++ test for albumin. The sediment was reported to contain innumerable bacteria.

The bleeding was stopped shortly after entry, and a whole-blood transfusion was administered. Two

sudden appearance of the nephrosis. A single examination of the urine was negative on admission, with the subsequent appearance of albuminuria following the administration of sulfonamides and blood. There was no evidence of a hemolytic reaction. And although a transfusion reaction was ruled out, we did not know what the influence of the sulfonamides was. We were strongly enough impressed to stop the sulfonamides, however.

DR ROPES: I neglected to mention the Congo-red test, which I thought was confirmatory evidence of amyloidosis. Retention of 67 per cent of the dye in the tissues, leaving only 33 per cent in the serum, is certainly presumptive evidence of the presence of amyloid.

DR BEVERLY TOWERY: Is there any evidence that Amigen or acacia influences amyloid disease?

DR ROPES: I do not know whether acacia does, but the repeated injection of sodium caseinate is one of the best ways of producing the disease experimentally in animals.

CLINICAL DIAGNOSES

Chronic ulcerative colitis

Nephrotic syndrome

Amyloid nephrosis?

Postoperative ileus

DR ROPES'S DIAGNOSIS

Chronic idiopathic ulcerative colitis, with secondary amyloidosis

ANATOMICAL DIAGNOSES

Ulcerative colitis

Amyloid degeneration of kidneys, liver, spleen and adrenal glands

Operation ileostomy, recent

Pulmonary embolus, with infarction of lung, small

Organizing thrombus of both common iliac arteries and inferior vena cava

PATHOLOGICAL DISCUSSION

DR MALLORY: At autopsy the peritoneal cavity was perfectly clean. There had been no peritonitis or mechanical obstruction following the ileostomy, and the dilatation of the small bowel must have been of a reflex origin. The entire large bowel was involved in a severe ulcerative process. The mucosa was markedly atrophied but showed an occasional bridge of mucosa across an area of ulceration. There was no ulcerative process in the ileum. Although the wall of the terminal segment of the ileum was edematous and thickened, it showed no amyloid. The liver was large, weighing 2500 gm, and was somewhat pale but not yellow or greasy and, we thought, not significantly fatty on gross examination, it was firmer than normal, and the markings were unusually prominent. We suspected amyloid, which was borne out by the histologic examination — in fact, there was rather extensive involvement in the liver. The spleen was large and showed typical

sago bodies characteristic of amyloid deposits in the malpighian corpuscles. The kidneys were markedly swollen, their combined weight being 600 gm, the cortex was extremely pale and thickened to 9 or 10 mm.

DR WADE VOLWILER: Did the acacia still remain in the organs?

DR MALLORY: It is not easy to see, I could not pick it out. The kidneys, as far as I could determine, represented a pure amyloid nephrosis. There were only moderate deposits of amyloid in the glomeruli but marked secondary degeneration of the tubules, especially the proximal convoluted tubules, as well as markedly dilated lumens containing a great deal of precipitated protein and much swollen epithelium. There was nothing to suggest a hemoglobinuric nephrosis or, so far as I could see, sulfonamide reaction.

There was a small pulmonary embolus, with a corresponding area of infarction, in the right lower lobe. The source of the embolus was a large thrombus that had almost completely occluded the lower 15 cm of the inferior vena cava and both common iliac veins.

As Dr Ropes pointed out, amyloid is an unusual complication of ulcerative colitis. I cannot remember having seen it before.

DR AUB: Was there any amyloid in the small intestine?

DR MALLORY: No, there was, however, severe amyloid disease of the adrenal glands — enough to make me wonder if the patient had had adrenal insufficiency.

A PHYSICIAN: Were anaerobic cultures made of the fluid draining from the anal sinuses?

DR MALLORY: No effort was made to culture the pus. Such sinuses are not a rare complication of idiopathic ulcerative colitis. They sometimes extend quite a distance on either side of the anus. We have seen cases in which both buttocks were almost completely destroyed.

CASE 33022

PRESENTATION OF CASE

First admission. A sixty-three-year-old postal clerk entered the hospital because of pain and numbness of the feet and shoulders.

Fourteen years before admission the patient was found to have had glycosuria without hyperglycemia. Two years later he entered a hospital because of hematuria. Diagnoses of diabetes mellitus and ureteral stone were made, and a right ureterolithotomy was performed. At the time of discharge the blood sugar was normal, and there was no glycosuria. For the following twelve years the patient was well. He took no insulin and ignored his diet. Five months before admission, on the way home from work, he became dizzy, felt tired and

In addition, the patient had diabetes and hypertensive heart disease, with cardiac enlargement and failure

DR JACOB LERMAN How do you explain the electrocardiographic findings unless he was taking digitalis or had a coronary infarct?

DR SHORT I am not an electrocardiographer, but believe that this patient's tracing was not specific for coronary disease, it may have been compatible with hypertension or myocardial disease and could have followed the administration of digitalis

CLINICAL DIAGNOSES

Hypertensive heart failure

Uremia

Diabetes mellitus

DR SHORT'S DIAGNOSES

Chronic pyelonephritis

Diabetes

Hypertensive heart disease, with cardiac enlargement and failure

ANATOMICAL DIAGNOSES

Chronic glomerulonephritis, inactive

Cardiac hypertrophy

Coronary sclerosis

Chronic passive congestion

Benign hyperplasia of prostate

(Diabetes mellitus)

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY It is always a difficult clinical problem to decide what type of renal insufficiency will be found in a case of this sort. Sometimes, it is equally difficult or even quite impossible after one has seen the results of post-mortem examination. Dr Short decided to rule out intercapillary glomerulosclerosis—the Kimmelstiel-Wilson syndrome*—and was correct in so doing. A small number of glomeruli in the kidney showed slightly suggestive changes, but no more than one might find in any diabetic patient. That certainly was not the major cause of the trouble. The kidneys were markedly contracted, their combined weight being

only 100 gm. The surface was pitted and scarred, and the cortex was reduced to 2 mm in thickness. On microscopic examination the outstanding phenomenon was that almost every glomerulus was surrounded by a crescent of collagen that lay within and obliterated Bowman's capsule. I do not see how this could have been produced except by a capsular glomerulonephritis. The epithelial cells lining the capsule first proliferate and later give way to fibroblasts which lay down collagen. I am therefore quite content in this case to commit myself to a diagnosis of old chronic glomerulonephritis. I think that it is still within the limit of possibility that other pathologists would interpret this case differently. The patient had the basis for a pyelonephritis in the form of a hypertrophied prostate, cystitis, dilatation of the ureters and slight dilatation of the pelvis of the kidneys.

The heart was enlarged, presumably secondarily to the hypertension. The coronary arteries were markedly sclerotic and narrow but not occluded at any point. The myocardium, particularly the interventricular septum, showed slight patchy discoloration on gross examination and slight focal degeneration on microscopic examination. There was not, however, any significant area of infarction. The lungs and the liver both showed severe chronic passive congestion.

In a case of chronic renal insufficiency we always look with interest at the parathyroid glands. The first person who searched for them in this case did not find them, which I think is evidence that they were not markedly enlarged. Dr Castleman made a secondary search and found two glands of normal size and a tumor nodule measuring 1.0 by 1.5 cm. This turned out to be an interesting curiosity. The sections showed the characteristic picture of a fetal lung, with well formed bronchi and alveolar spaces lined with cuboidal epithelium. This is an infrequent but not extremely rare congenital anomaly. One hardly expects to find it in a seventy-year-old man, however, or as high in the neck as this one was. When bronchial buds grow into extrapleural tissues a small growth of lung tissue may occur, but since the lesion is extrapleural, it never expands and maintains the character of a fetal lung. In this case it was a coincidental lesion of purely pathological interest.

*Kimmelstiel, P., and Wilson, C. Intercapillary lesions in glomeruli of kidney. *Am. J. Path.* 12: 83-98, 1936.

days later the nonprotein nitrogen was 70 mg, and the fasting blood sugar 132 mg per 100 cc. The carbon dioxide combining power was 27.1 milliequiv per liter. The chloride was 106 milliequiv per liter, and the total protein 6.4 gm per 100 cc.

The nonprotein nitrogen level doubled in two days, reaching 145 mg per 100 cc, whereas the carbon dioxide dropped to 25 milliequiv per liter. The patient became comatose and died on the fourth hospital day.

DIFFERENTIAL DIAGNOSIS

DR CHARLES L. SHORT: In the first place, we must assume that this patient had diabetes on the basis of the history and the laboratory findings. This diagnosis was first made eighteen years before final admission, but he was under treatment for only six years. The diabetes was complicated at one point by neuritis, which was symptomatically relieved by therapy, and eye-ground changes consistent with diabetic retinopathy. The patient died in cardiac failure, the heart disease evidently being secondary to the long-standing high blood pressure. The episode five months before the first admission, when he suddenly developed weakness, dyspnea and palpitation, suggests a coronary occlusion, although he did not have actual pain. The clinical picture, however, and the electrocardiogram do not seem characteristic of that condition.

The real problem, it seems to me, is to determine the nature of the renal lesion. We might briefly recapitulate the course of the kidney disease at this point. Eighteen years before admission the patient had hematuria and a right ureteral calculus was removed, but no note is made of the blood pressure at that time. About twelve years later, he was found to have albuminuria and severe hypertension, so that there is no clue regarding whether the hypertension preceded the renal disease or vice versa. At the time of the first admission, red cells and casts were found in the urinary sediment, and nitrogen retention had already been noted. X-ray studies disclosed a left kidney that seemed to be of normal size, but the right kidney was not visible. Since the x-ray films are not here, I shall assume that they add nothing to the written report. I do not believe that we can draw any conclusion from the failure to see the right kidney, it may simply have been obscured. At that time the patient again showed marked hematuria, he was apparently well for five years, and the kidneys regained adequate function, since the nonprotein nitrogen was normal. A year before death he developed cardiac failure and finally uremia, which presumably accounted for the anemia and bleeding. At the final admission he continued to have albuminuria, and the sediment for the first time contained many bacteria.

A number of types of Bright's disease can produce a terminal picture of hypertension and uremia. I do not need to list them all, but I shall mention some

of them in the differential diagnosis. Since this patient was diabetic, one thinks of the renal lesion associated with diabetes — namely, intercapillary glomerulosclerosis. It would be hazardous to say that this condition was not found to some extent histologically in this patient, since certain authors report its presence, to some degree, in at least half the diabetic patients at autopsy. Slight glomerulosclerosis may also be found in nondiabetic patients. I hope that Dr. Mallory will comment on this point later. We are trying to determine the important cause for the renal failure, and I am therefore going to discard this condition as having been primarily responsible, chiefly because at no time did the patient present the nephrotic picture that is often associated with severe degrees of intercapillary glomerulosclerosis. The fact that he once had swelling of the face may represent renal edema, but I do not believe that we are justified in making this diagnosis merely because the patient was diabetic. Swelling of the face is suggestive of glomerulonephritis, but there was no definite history of an acute attack, so that we have no knowledge that the kidney disease preceded the hypertension. Nephrosclerosis or vascular nephritis is probably as good a bet as any, and in any event autopsy probably showed arteriolar changes in the kidneys in view of the long-standing hypertension. As a fundamental cause of the renal insufficiency, however, I am more in favor of a condition that has been recognized accurately only in recent years as an important cause of kidney disease and hypertension. I refer to pyelonephritis, which, in a chronic or healed stage, may result in the terminal picture shown by this patient. The ureteral calculus eighteen years before death may have been highly significant, either as a primary cause of obstruction and infection or on the basis of a preceding infection. It is true that the patient gave no history of an acute pyelonephritis, but such a history is not elicited in most cases. The urinary sediment showed no definite evidence of infection until just before death. Cultures at the first admission were negative, but the process may have been relatively quiescent or healed at that time. The hematuria, which may also have been due to recurrent urinary calculi, is sometimes prominent in this form of nephritis. Pyelograms at the first admission would have been helpful and perhaps diagnostic, although cases of pyelonephritis have been reported with negative x-ray findings. The fluctuation in the course of the disease and the return of adequate function after uremia had set in are compatible with pyelonephritis. At the final admission the nocturia and frequency, the urinary picture, the prostatic hypertrophy and the enlargement of the bladder suggest that another factor was involved in the last part of the illness — namely, an obstructing prostate with infection behind it. I realize that this is a somewhat slender chain of evidence, but chronic or healed pyelonephritis is my first choice.

laborative study by members of the New York Department of Health and by Drs Heubner and Armstrong of the National Institute of Health is undertaken.

At the National Institute of Health, an organism was isolated that possessed the morphologic, cultural and staining characteristics of the rickettsias. This organism was recovered from the tissues of a guinea mouse, which had been inoculated with blood drawn on the second day of fever from one of the patients. It produced illness in mice and guinea pigs and grew well in the yolk-sacs of fertile eggs. Further extract yolk-sac antigens were then prepared, and these were shown to fix complement when mixed with serums drawn from convalescent cases. This complement-fixation reaction was apparently specific so far as it was tested, except for cross reactions with serums from patients with Rocky Mountain spotted fever.

The agent was also isolated from a saline suspension of tissues of mites (*Allodermomyssus sanguineus*) collected in the house of the patient from whose blood the original rickettsia was obtained⁵ and a similar rickettsia was recovered from a mouse that was bitten by one of these mites. The strains isolated from the mite and from the mouse were identical with the one obtained from the patient. The identity of the strains was also established by the fact that each established a solid cross immunity in guinea pigs.

Because of the vesicular appearance of some of the lesions, the disease was called "rickettsialpox," and since the agent was isolated from mites, it was named *Rickettsia akari*, after the Greek name for mite. The recovery of apparently identical strains of rickettsia from the blood of a man ill with rickettsialpox and from blood-sucking mites collected from the home of the same man indicate that human infection was acquired from the mites, probably through biting.

The increase in the frequency with which Q fever has been observed in this country and the isolation of this new strain of rickettsia from a case of an entirely different type of disease in New York City both point to the increasing importance that rickettsias are assuming as causes of disease in the United States.

THE MEANING OF PSYCHOSOMATIC MEDICINE

CURRENT medical literature is marked by the number of articles on psychosomatic medicine. Although this is an indication of a healthy interest in the relation between psychic and somatic factors, which pervade sickness of all kinds, some of these articles suggest that there is occurring a subtle revision of the original meaning of the term "psychosomatic," which, if it becomes established, may do great harm. This is a matter of general interest and of basic significance.

When the term was first promulgated it was on the basis that disease of whatever kind always included in its manifestations elements of both somatic and psychic origin. Although the bodily aspect might have been in some cases the precipitating cause, it was thought that psychic disturbances always were included in the complete pattern of the disorder. In the same way, when psychic factors dominated the inception of an illness somatic disturbances always occurred and contributed their part to the manifestations of the disorder. Psychosomatic medicine therefore meant that disease is never wholly somatic or entirely psychic; it is always, with certain limitations, a combination of both. To emphasize the absence of a dichotomy between the somatic and psychic factors the term was put forth with the hope that it would no longer be necessary to say, with Kennedy,¹ that, "lacking appreciation of the neurological aspect of all disease, for it must color all by pervading all, we must perforce regard our patients not as persons but as congeries of viscera imperfectly combined and inadequately framed in design."

What is happening to the term "psychosomatic" seems to be a revision of definition that makes it mean something quite different from what it did

A NEW RICKETTSIAL INFECTION IN NEW YORK CITY

DURING June and July, 1946, there appeared in New York City a peculiar febrile disease that aroused considerable interest and had both clinicians and laboratory workers temporarily baffled. The disease affected 92 residents of Kew Gardens in the Borough of Queens and 10 other persons elsewhere in New York City.¹⁻³

The illness was clinically characterized by an initial skin lesion on some part of the body. This appeared as a papule with surrounding erythema, was round or oval in shape and about 0.5 to 1.0 cm in diameter. Coincidentally the regional lymph nodes became enlarged and sometimes slightly tender. The patients, however, usually did not feel

sick, and they continued to work until five to ten days later, when there was an acute onset of chills, fever, sweating, headache and backache. The chills were often repeated several times a day, with temperature rises to between 102 and 104°F and remissions to 99 or 100°. The headache was usually quite severe. About three or four days after the onset of these symptoms a rash appeared over the body. The individual lesions were maculopapular and varied from 2 to 5 mm in diameter, some were flat, others somewhat pointed. Frequently, a deep-seated vesicle was seen in the center of the lesion, which often broke down and formed a crust. The fever, rash and other symptoms usually lasted from four days to a week. Although the patients felt sick, they did not usually appear particularly toxic at any time during the entire illness. The spleen was palpable in about half the cases but was never large.

Laboratory examinations were of no great help. The urine was usually normal. White-cell counts showed a leukopenia, with either a normal differential count or a lymphocytosis. Blood cultures were sterile. There was no increase in heterophil antibodies. The serums in both the acute and the convalescent stage showed no agglutination of typhoid and paratyphoid bacilli, the organisms causing brucellosis and tularemia, *Proteus X-19* or leptospira. Complement-fixation tests were negative for typhus fever, Rocky Mountain spotted fever, Q fever, scrub typhus and psittacosis.

Epidemiologically the cases were interesting because the majority of them were reported from one group of buildings in a section of Kew Gardens. Although the physicians who saw these cases had patients in other buildings in the immediate neighborhood and in areas nearby, they saw no other cases. Single cases, however, were observed by physicians of the New York City Department of Health in Manhattan and in the Bronx.

There were no fatalities, and no complications were observed in any of the cases. The disease did not respond to antibiotic or other specific therapy, and most of the cases were treated symptomatically.

The entire picture of the disease strongly suggested a rickettsial infection, and since all the tests for known diseases were negative, the aid of the National Institute of Health was enlisted. As a result, a

th and to improve medical care, these facts will be preceded by an official representative of the state medical association. The broadcasts should accomplish much in informing the public concerning the remarkable advances in medicine that have been made during the last hundred years and the facilities that are now available to raise the health standards of the Nation, and they are, of course, particularly appropriate for the centennial year of the American Medical Association. The first was given from 4:00 to 4:30 p.m. (EST) on Saturday, December 7, and one has been given or is scheduled on each following Saturday. The final broadcast, the twenty-sixth, will deal with the hundred years of the American Medical Association from a nationwide standpoint. To ensure a large audience, all physicians in each section are urged to publicize its program, the date of which will be published in the *Journal of the American Medical Association*.

JTE

The following appointments to the teaching staff of Harvard Medical School were recently announced: Max Boravk, of Newton Highlands (A.B. Harvard University 1930, D. Harvard University 1934, Ph.D. Columbia University 1938), assistant professor of bacteriology and immunology, etc. Lehner Bibring, of Cambridge (M.D. University of Vienna 1924), associate in psychiatry, Seymour Jerome Gray, Washington, D.C. (A.B. University of Rochester 1933, D. University of Pennsylvania 1936, Ph.D. University of Chicago 1945), assistant professor of medicine, Marian Abot Putnam, of Milton (A.B. Radcliffe College 1917, M.D. Johns Hopkins University 1921), lecturer on psychiatry, Edwitt Stetten, Jr., of New York City (A.B. Harvard University 1930, M.D. Columbia University 1934, Ph.D. Columbia University 1940), assistant professor of medicine.

CORRESPONDENCE

CONVALESCENT HOMES

To the Editor: The Committee on Public Health Relations of the New York Academy of Medicine is preparing a new edition of the *Directory of Convalescent Homes in the United States*, to be published by the Sturgis Fund of the Winifred Easterson Burke Relief Foundation of White Plains, New York. The last issue of this directory was published by the Sturgis Fund in 1931 under the auspices of the Committee on Convalescent Care of the American Conference on Hospital Service and has long been out of print. The need of a new directory is recognized by all concerned.

Early in January, a questionnaire will be distributed to all recognized convalescent homes maintained by municipalities, counties or voluntary bodies. The information sought deals with the physical plant, the staff, the requirements for admission, the type of patients, therapy and such other matters as will make the directory a dependable guide for physicians who wish to refer their patients to institutions for convalescence. The questionnaire is so devised that it can be filled out with a minimum of effort. Convalescent homes that do not receive a questionnaire are urged to request one by writing to E. H. L. Corwin, Executive Secretary, Committee on Public Health Relations, New York Academy of Medicine, 2 East 103 Street, New York 29, New York.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

The Psychoanalytic Study of the Child Volume 1 (1945) 8°, cloth, 423 pp. New York: International Universities Press, 1945. \$6.00.

This is the first volume of a new series of studies on child analysis and child guidance. Various authors, in both America and Europe, report on many aspects of a pertinent problem. The book is designed for the specialist, and as a survey of the work now being carried on in psychoanalysis, as applied to children, can be fully recommended. Most of the papers are supplied with bibliographic references, and the work has been carefully edited.

Essentials of Neuro-Psychiatry. A textbook of nervous and mental disorders. By David M. Olson, M.D., associate professor of psychiatry, University of Illinois College of Medicine. 8°, cloth, 310 pp., with 138 illustrations. Philadelphia: Lea and Febiger, 1945. \$4.50.

The author presents an exposition on the principles involved in the psychiatric studies of mental disorders. The text is complete, with many illustrations and references to the literature. The volume is a sound contribution to the subject from a modern point of view. In spite of the fact that the book covers only three hundred pages, the material is surprisingly comprehensive and the author shows evidence of a thorough grasp of his subject.

Rorschach's Test. Volume II. A Variety of Personality Pictures. By Samuel J. Beck, Ph.D., head of Psychology Laboratory, Department of Neuropsychiatry, Michael Reese Hospital, Chicago, and associate professor of psychology, Northwestern University. With a foreword by Roy R. Grinker, M.D. 8°, cloth, 402 pp. New York: Grune and Stratton, 1945. \$5.00.

This is the second volume of a study on the Rorschach test. In the first, the author gave details regarding the method used in testing. He now presents an interpretation of his findings, giving many case histories to illustrate his points. There is a careful evaluation of clinical material with an analysis of the records. The book is well printed and there is an extensive bibliography. It should be of value to other workers in the same field.

New Directions in Psychology toward Individual Happiness and Social Progress. By Samuel Lowy, M.D. With an introduction by Herbert Read. 8°, cloth, 194 pp. New York: Emerson Books, Incorporated, 1945. \$3.00.

This volume is based on a series of lectures given by the author in Czechoslovakia between 1930 and 1936. He has had wide experience in European countries and more recently, in the last four years, in Great Britain, where he has been associated with the Czechoslovakian Center in Manchester. The author has analyzed a large number of patients from different countries, and his book reflects a careful evaluation of this material. Much of the text relates to the social aspects of psychiatry, and the author goes deeply into the philosophic principles of racial relations, tolerance, psychology and similar subjects associated with the problems of readjustment, particularly of displaced persons.

Manual of Diagnosis and Management of Peripheral Nerve Injuries. By Robert A. Groff, M.D., and Sara J. Houtz, B.S. With an introduction by I. S. Radwin, M.D., John Rhea Barton Professor of Surgery, University of Pennsylvania School of Medicine. 8°, cloth, 185 pp., with 111 illustrations. Philadelphia: J. B. Lippincott Company, 1945. \$8.00.

The subject is well covered by this brief monograph, the result of war experiences with patients having injuries to the peripheral nerves. The conclusions, in general, are sound. The simple line drawings, illustrating examination and various types of injury, are excellent. The format leaves a good deal to be desired. Although the subject is fully reviewed, it does not add much new material to knowledge of injuries of the peripheral nerves. Most physicians will not agree with the statement that electrotherapy, in facial paralysis, "can do more harm than good in maintaining muscle tone and assisting restoration of muscle action."

originally. Thus, Menninger² implies that what he means by psychosomatic medicine comprises the organ neuroses. It is not likely that he intended to give quite this impression, but his article serves as an illustration of a growing tendency to limit, if not to redefine, the term. Such a redefinition would restrict the term to those disorders that are thought to be psychic in origin and somatic in manifestation. This does not appear to conform to the original meaning; it is a revision, if not a distortion.

Not only does this alteration warp the conception so well presented by Dunbar³ in her book *Emotions and Bodily Changes*, but it threatens to undo the good work that she initiated. The former rigid classification of disease as either somatic or psychic is no longer tolerable in the light of present-day concepts. Dunbar's book pointed this out and set the course of medicine in the proper direction. It is regrettable that through misunderstanding or lack of clarity so many writers are upsetting the concept that all disease is both somatic and psychic. Restriction of the term "psychomatic" to the somatic manifestations of psychic disorders will, if it persists, materially delay general realization of the true nature of disease and will necessitate the classification of disease as somatic, psychic and psychosomatic. This would be regrettable.

Many examples of this process of revision could be given. With characteristic enthusiasm, clinicians seem to be forming a cult, glibly using the latest catchword without taking the trouble to understand its meaning. It might even be better if psychosomatic were abandoned and the simple word "sick" or some synonym were to be used. If it were understood that to be sick is to be assailed by influences derived from and expressing elements of both mind and body, the clinician might find it less convenient to fit the condition of the patient into any rigidly defined category. It would then be easy and natural to regard the patient as a person, as suggested by Robinson,⁴ and to look for all the elements that go to form the complex of his disease. It would also be easy and natural to realize that what often passes for mental disease is quite likely to result from organic causes and that organic expressions of disorder often result from psychic causes. Beyond all this it would be both easy and natural to realize

that all disease is compounded of both bodily and mental factors.

One of the great medical achievements of the past few years has been the recognition of the part played by the emotions in disorders that were previously regarded as solely organic. Perhaps an achievement of equal importance will come from the realization of the part played by organic factors in what now is considered to be solely mental disease. If it is too late to undo the harm caused by the subtle revision of the term "psychosomatic" then it may be necessary to devise an alternative. Thus, if psychosomatic is to be confined to organic disorders arising from psychic causes, then it may be counteracted by some such term as "somatopsychic" to be used in connection with mental diseases of somatic origin. It is hoped that no such clumsy circumlocution will be needed. No occasion for it will exist if the original meaning of psychosomatic is not distorted. After all, this word obviously was introduced in this form for the sake of euphony and not because of any design ascribing to one factor priority over the other.

DEATH

KANE — WILLIAM V. Kane, M.D., of Lynn, died October 11. He was in his fifty-fifth year.
Dr. Kane received his degree from Tufts College Medical School in 1915. He was a member of the New England Pediatric Society.

MISCELLANY

"DOCTORS — THEN AND NOW"

The 1946-1947 program of broadcasts sponsored by the American Medical Association and the National Broadcasting Company will trace the highlights in medical progress in the United States since pioneer days. The whole country has been divided into twenty-five sections, and in each a dramatization of some local event that contributed to the advance of medical knowledge will be given. Thus, in the section composed of Massachusetts, Rhode Island and Connecticut the story will concern Oliver Wendell Holmes' contribution to the conquest of puerperal fever and his coining of the word "anesthesia," whereas in Maine, New Hampshire and Vermont the story will be based on Nathan Smith's efforts that led to the formation of highly successful medical schools at Dartmouth College, Yale University, Bowdoin College and the University of Vermont. At the close of each dramatization the program will conclude with up-to-the-minute news of what is now being done in each particular section to further medical knowledge, to promote public

EPIDEMIC DIARRHEA OF THE NEWBORN IN MASSACHUSETTS

A Ten-Year Survey

A DANIEL RUBENSTEIN, M D,* AND GEORGE E. FOLEY†

BOSTON

EPIDEMIC diarrhea of the newborn continues to be a major problem in infant care. Although the clinical manifestations of the syndrome have been adequately described, outbreaks frequently remain unrecognized until widespread dissemination has taken place, and the occurrence of fatalities has stimulated the adoption of belated control measures. Unfortunately, when epidemics are insidious in onset, the diagnosis may not be easy. For this reason those responsible for the care of newborn infants must be constantly on the alert to differentiate the syndrome from the large variety of other conditions producing diarrhea in infants.

The etiology of epidemic diarrhea of the newborn has not been determined. A striking characteristic of many of the outbreaks previously reported in the literature is the diversity of agents suspected as the cause, various authors having reported the isolation of the following micro-organisms: *Shigella dispar*,¹ *Sh. paradyserteriae*,² *Klebsiella pneumoniae*,³ gamma streptococci,³ *Escherichia coli mutabile*,⁴ monilia,^{5, 6} *Esch. coli*,⁷ *Pseudomonas aeruginosa*,⁷ alpha streptococci,⁷ *Aerobacter aerogenes*,⁸ *Proteus vulgaris*,⁹ and filterable agents.¹⁰⁻¹² The lack of a common etiology in the reported epidemics suggests that epidemic diarrhea is caused either by a single agent as yet unknown or by a variety of organisms whose toxic products result in gastrointestinal irritation. The former thesis is favored by the isolation of filterable agents in recent outbreaks,¹⁰⁻¹² and the latter by the similarity of histologic changes observed in fatal cases associated with a variety of micro-organisms.¹³

It is the purpose of this discussion to review nineteen outbreaks of epidemic diarrhea of the newborn as reported to the Massachusetts Department of Public Health from 1935 to 1945. In the 258 cases reported during the period of the study 85 patients died, giving a case mortality of 33 per cent (Table 1).

In addition to the clinical and epidemiologic investigations, bacteriologic studies were undertaken to evaluate the adequacy of nursing technics and formula-making procedures and to study possible modes of transmission from infant to infant. Direct observations of nursery technics were checked by a few simple examinations such as bacterial counts on formulas and cultures of thermometers, nipples and other utensils. Cases and contacts, including nursery personnel, were studied bacteriologically, type determination being utilized as an epidemiologic tool whenever possible.

In several outbreaks nose and throat cultures were obtained from patients and contacts. Stool cultures were studied for the presence of streptococci and to exclude the possibility of infection with enteric micro-organisms.

Since there is no practical method for the serologic classification of *Staphylococcus aureus*, the strains encountered in the outbreaks reported were studied biochemically. The ability of a group of strains to utilize various polysaccharides was taken as an indication of common identity. Whenever possible the serologic grouping of streptococci¹⁴ and the determination of types within the various groups,¹⁵ especially those contained in Lancefield Group D,^{16, 17} were employed to establish the common identity of the strains concerned in a single outbreak.

During the course of these investigations, a method was evolved for scoring the efficiency of technics of individual nurseries in handling newborn infants. The details of this method are outlined below, together with an appraisal of procedures encountered in the hospitals where outbreaks occurred.

CLINICAL STUDIES

The syndrome known as epidemic diarrhea of the newborn primarily affects infants up to three weeks of age. It was frequently observed that infants developed symptoms following discharge from an infected nursery and were admitted to open wards

ANNOUNCEMENTS

Dr Archie A Abrams calls attention to the omission of his office address and telephone number from the current telephone directory. His office is at 1093 Beacon Street, Brookline, and the telephone number is ASPinwall 9951

Dr Stephen D Peabody, who has returned from military service, announces the opening of his office for the general practice of medicine at 7 Cross Street, Wellesley

SOUTH END MEDICAL CLUB

The next regular meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, January 21, at twelve noon. Dr Franz J Ingelfinger will speak on the topic "Developments in the Treatment of Peptic Ulcer and Its Complications."

Physicians are cordially invited to attend

NEW ENGLAND PEDIATRIC SOCIETY

A meeting of the New England Pediatric Society will be held on Wednesday, January 22, in Boston

PROGRAM

- 1 15 p m Luncheon at Vanderbilt Hall, Harvard Medical School (price, 70 cents)
- 3 30 p m Clinical presentation of patients Amphitheater, Joseph H Pratt Diagnostic Hospital. Members of the medical profession and students are invited to attend
- 5 30 p m Refreshments at Longwood Towers
- 6 30 p m Dinner at Longwood Towers (price, \$2 00, including tax). Members and their guests are invited to attend
- 7 30 p m Annual meeting Longwood Towers
- 7 45 p m The Management of Respiratory Diseases in Infants and Children Longwood Towers. Dr James L Wilson, professor, Department of Pediatrics and Communicable Diseases, University Hospital, University of Michigan. Members of the medical profession and students are invited to attend

ELLA SACHS PLOTZ FOUNDATION FOR THE ADVANCEMENT OF SCIENTIFIC INVESTIGATION

During the twenty-third year of the Ella Sachs Plotz Foundation for the Advancement of Scientific Investigation, forty applications were received by the Trustees, twenty-nine of which came from the United States, the other eleven coming from different countries in Europe, Asia and North and South America. Twenty grants were distributed.

Applications for grants to be held during the year 1947-1948 must be in the hands of the Executive Committee before April 15, 1947. There are no formal application blanks, but letters asking for aid must state definitely the qualifications of the investigator, an accurate description of the research, the size of the grant requested and the specific use of the money to be expended. In their requests for aid applicants should state whether or not they have approached other foundations for financial assistance and what other sources of support are relied on for research. It is highly desirable to include letters of recommendation from the directors of the department in which the work is to be done. Only applicants complying with the above conditions will be considered. Applications should be sent to Dr Joseph C Aub, Massachusetts General Hospital, Fruit Street, Boston 14.

SCIENTISTS NEEDED FOR USPHS

Competitive examinations will be held early in 1947 for appointment to the Regular Corps of the United States Public Health Service, according to a recent announcement by Dr Thomas Parran, Surgeon General. Seventy-five vacancies exist in grades of assistant and senior assistant scientist.

Written examinations, covering each candidate's particular field of science, as well as related fields, will be held April 14

and 15 at places mutually convenient to the applicant and the Service. Oral examinations will be held during the February 13-April 9 in thirty cities, strategically throughout the United States. (The oral examination of candidates from New England will be held in Boston at the Marine Hospital, 77 Warren Street, Brighton, on April 1.)

Commissions are available to scientists trained in any of the following fields: bacteriology, mycology, parasitology, entomology, malacology, biology, chemistry, physiology, physics, statistics (mathematical, demographic and so forth), psychology and milk and food examination. Assignments will be in line with demonstrated ability and experience.

An applicant for the grade of assistant scientist must be a citizen of the United States, have had seven years of educational and professional training or experience, possess a certificate or diploma from an institution of recognized standing and be able to pass a physical examination given by a medical officer of the United States Public Health Service. The same requirements, plus an additional four years of training or experience, apply to those seeking the grade of senior assistant scientist.

Commissioned officers in the Regular Corps enjoy the same benefits and privileges as do officers of the Army, Navy or Marine Corps. The grade of assistant scientist is equal to that of first lieutenant in the Army. Annual pay, with allowances for dependents is \$3811. A senior assistant scientist ranks with a captain of the Army and draws, with allowances for dependents \$4351 a year.

United States Public Health Service officers are entitled to full medical care and hospitalization for themselves and their families, including disability retirement at three-fourths basic pay. They receive thirty days' annual leave with pay. Periodic promotions are based on length of service and merit. The retirement age is sixty-four.

Application forms and additional information may be obtained by writing to the Surgeon General, United States Public Health Service, Washington 25, D C.

premature infants who were exposed 43, or 49 per cent, developed the infection. The rate among full-term infants was significantly lower: of the 680 infants exposed only 157, or 21 per cent, developed the infection. The case mortality among premature infants was 53 per cent, or more than twice that for full-term infants, which was 25 per cent. It is

artificially fed for several days during the first week of life.

Investigation of nursing technics and of methods of formula making brought to light many startling deficiencies. At times nursing procedures were found to be in direct violation of existing state regulations. In some hospitals so-called "aseptic technics," when

apparent that the former are particularly susceptible to epidemic diarrhea of the newborn, and that once the infection has been acquired death is likely to occur.

In two outbreaks it was noted that infants in adjacent bassinets developed the infection. By and large, however, such relations could not be established. Usually, both breast-fed and artificially fed

subjected to bacteriologic investigation, yielded results that were surprising to nursery supervisors and hospital administrators.

The findings concerning nursery and formula-making technics in ten hospitals in which outbreaks of epidemic diarrhea of the newborn occurred are presented in Table 3. A numerical value was assigned for each of the eight factors ordinarily

of another hospital before a clinical diagnosis had been made. No secondary cases occurred among older infants or hospital personnel known to have been exposed to these babies. Similarly, secondary cases were not discovered among family contacts.

Occasionally, infants beyond the neonatal age developed symptoms indistinguishable from epidemic diarrhea of the newborn. In one outbreak (Table 1, Outbreak 5) a seven-week-old infant became ill and died following exposure to patients

Some fatal cases occurred at the onset of an outbreak. Other early cases were not so serious, and mild infections continued to appear for several weeks before the occurrence of a fatal case. Secondary or recurrent outbreaks have been reported in a single institution after intervals of several months during which no new cases appeared.¹⁸

Once the existence of an epidemic has been established, the differential diagnosis is not difficult. Salmonella infection of the newborn, which may

with epidemic diarrhea of the newborn. The clinical picture was identical with that shown by younger infants.

The onset of the infection may be insidious or abrupt. In some outbreaks early cases may be difficult to detect. Infants may become indifferent to food and fail to gain weight. They appear listless, and vomiting is occasionally noted. When the onset is sudden, profuse diarrhea and vomiting may be the first signs, followed by a dramatic loss in weight.

Characteristically, the stools are frequent, watery and yellow in color, changing later to green. Blood and pus are not usually present. As the diarrhea persists, the infant becomes dehydrated and loss of weight of a pound a day may occur.

Marked elevation of temperature is not a prominent feature. At times, even in fatal cases, the temperature remains normal or only slightly elevated until just prior to death, when there is a rise associated with a terminal bronchopneumonia.

Severe cases are unmistakable. The infant rapidly becomes worse, vomiting is severe and diarrhea profuse. Dehydration is serious, and the fontanels are sunken. Death may occur in twenty-four hours or may be deferred for several days. The total duration of illness in 25 fatal cases varied from two to twenty-nine days, with an average of eight days.

also occur in outbreaks, must be differentiated from epidemic diarrhea of the newborn. In the former disease the onset is abrupt, with a marked elevation of temperature. Although the initial manifestations may be gastrointestinal, the subsequent clinical course is sometimes characterized by bacteremia and sepsis, with signs and symptoms of meningitis, pneumonia or otitis media. At least two Salmonella outbreaks among the newborn have been reported in which meningitis was the principal clinical manifestation.^{19, 20} Cultures of the blood and stools readily establish the diagnosis in such epidemics.

It must be pointed out that clinically and epidemiologically the outbreak described by Buddingh and Dodd¹⁰ presents certain features that differentiate it from the syndrome under consideration. Secondary cases developed among hospital personnel, and thrushlike lesions, which are not ordinarily encountered in patients with epidemic diarrhea of the newborn, were described. Buddingh's virus was demonstrated by scarifying the cornea of a rabbit.

EPIDEMIOLOGY

Previous reports have called attention to the high morbidity and mortality associated with epidemic diarrhea of the newborn.^{18, 21} Similar high rates were experienced in Massachusetts (Table 1). Morbidity rates varied from 10 to 60 per cent, and case

esulted in contamination of the formulas. In other hospitals student nurses, after twenty-four hours of instruction, took complete charge for one or two months, and were then replaced by other students. In only four hospitals was a single person — a

respiratory tracts or the stools of the personnel (Table 6)

According to standard practice, formulas should not be prepared in a room that also serves as a diet kitchen for adjacent hospital wards. This requirement was satisfied in only two of the ten hospitals. In the majority a single refrigerator was used both for the storage of food for patients and for the infants' formulas.

Procedures for the sterilization of nipples varied considerably. In three hospitals nipples were boiled once in twenty-four hours and thereafter kept in a so-called "sterile container" to be used as needed. In other nurseries, nipples were boiled immediately after each feeding, following which they were stored in sterile containers for two or three hours until a subsequent feeding.

Examination of nipples sterilized and stored in this manner frequently revealed the presence of large numbers of bacteria, on both the inner and the outer surfaces. In Nursery A, for example (Table 6), cultures of supposedly sterile nipples and of a sterile funnel used in filling nursery bottles revealed the presence of pure cultures of *Staph aureus*. These strains were biochemically identical with those isolated from the throats of 2 infants and from the hand dip in use in this nursery.

Ordinarily, nipples are handled with sterile forceps kept in a jar of disinfectant. This practice is bac-

registered nurse or a dietitian — charged with the responsibility of formula preparation and of the instruction of student nurses.

Samples of formulas were submitted from several of the nurseries studied. Instead of being almost bacteria free, as should have been expected, they gave bacterial counts that would scarcely have

regarded as significant in infant care. A score of 10 was granted for each of six items. Adequacy of nursing staff and of supervision of formula making was considered of extreme importance and was assigned a value of 20. It will be noted that no hospital received a score higher than 80. Perhaps it was only a coincidence that there were no fatal cases in any of the outbreaks occurring in hospitals with a score of 50 or higher.

Although the use of a common rectal thermometer is contrary to existing regulations, in seven of the nurseries individual thermometers were not available

individual cup generally recommended for this purpose.

It is customary in many nurseries for nurses to dip their hands in a so-called "sterilizing" solution (usually alcohol) after handling each infant and before picking up another. Cultures of several of these sterilizing solutions revealed exceedingly high bacterial counts (Table 4). Like the thermometer solutions, the hand dips were often used for several days without being changed. It was frequent practice in some nurseries to filter the used alcohol hand solution. This recovered alcohol was sub-

for each infant. In several of these hospitals, immersion of the thermometer in a bichloride or alcohol solution, frequently before removal of the lubricating material, was the method employed in sterilization.

The thermometer dips used in two of the nurseries studied were subjected to bacteriologic examination (Table 4). Both nurseries used a 1:10,000 dilution of bichloride of mercury for this purpose. The lubricant was wiped off with a pledget of cotton, and the thermometers were then soaked overnight in a common basin of bichloride solution. This was renewed once in seven or ten days. Bacterial counts on samples of one of these thermometer dips revealed a bacterial population of 7,000,000 viable micro-organisms per cubic centimeter, the majority of which were *Esch coli*.

Similar studies on samples of the thermometer solution taken from a second nursery revealed a count of 44,000 viable micro-organisms per cubic centimeter, of which the majority were *Esch coli*, *Pr vulgaris* and *Staph albus*. It is obvious that thermometers treated in this manner could readily transmit infection from infant to infant.

Standard nursing technics attempt to limit contact between infants wherever possible. The use of common utensils and materials should be avoided. In several nurseries, a common oil bottle served as a ready means of maintaining contact between infants. The oil bottle was used instead of the

sequently added to a fresh supply for the following day's use.

Adequate space was available in only three out of the ten nurseries. The Children's Bureau²² has recommended 30 square feet per bassinet in hospital nurseries. Several of the nurseries were obviously overcrowded. In three, there was scarcely enough room for a nurse to pass between the rows of bassinets.

What constitutes an adequate nursing staff in an infant nursery? The Children's Bureau²² recommends that a nurse should not be responsible for the care of more than 8 infants. It is apparent that most hospitals have not adopted so high a standard. For the purpose of this study, an arbitrary standard of 1 nurse for 12 babies was considered satisfactory, provided that this ratio was maintained both day and night.

The nursing staffs were considered adequate according to this standard in only three out of the ten hospitals studied. One institution, with a daytime ratio of 1:12, employed but 1 nurse to care for 24 infants during the night. The daytime ratios varied from 1:5 to 1:20, whereas at night the range was from 1:12.5 to 1:26.

In six of the ten hospitals, formula preparation was not adequately supervised. In two, untrained ward attendants were responsible for this important procedure. Observation of these persons at work revealed faulty practices that could easily have

resulted in contamination of the formulas. In other hospitals student nurses, after twenty-four hours of instruction, took complete charge for one or two months, and were then replaced by other students. In only four hospitals was a single person—a

satisfied the minimum market requirements for raw milk (Table 5). A large variety of organisms were recovered from these formulas. In several cases the bacteria were of the same species as those isolated from infants in the nursery, as well as from the

terrologically unsound not only because it places too much dependence on the efficiency of chemical disinfectants but also because the manipulation necessary to replace the nipple on the bottle involves considerable risk of contamination from the fingers.

of the nurse. In only four nurseries were nipples adequately sterilized prior to each feeding.

Pasteurization or autoclaving of formulas after the bottles have been filled is an excellent safeguard in the feeding of the newborn in hospitals. Bottles are capped with sterilized nipples, and aluminum or glass caps are placed over the rubber nipples, from which they are separated by a pledget of cotton. The aluminum or glass-capped bottles are then placed in an autoclave and sterilized at 7 pounds of pressure for twenty minutes. This precaution eliminates the possibility of any contamination that may have taken place during the preparation of the formulas.

DISCUSSION

Since both the etiology and the manner of spread of epidemic diarrhea of the newborn are unknown, adequate supervision of nursery-room technics and methods used in formula preparation constitutes a safeguard against the occurrence of outbreaks. The studies described above revealed the need for greater diligence on the part of nursery supervisors. Careful attention to nursery technics should be part of the routine of every hospital. Too often it is only after the occurrence of an outbreak that authorities become aware of such matters.

Superintendents of hospitals frequently do not seek assistance from health agencies in controlling outbreaks until after considerable time has elapsed. Only six outbreaks (Table 7) were reported within

of the first case and that of the last fatal case were noted in several outbreaks. It is apparent that epidemics are frequently of long duration, and it is conceivable that many cases might have been prevented by the early adoption of drastic control measures.

Several of these outbreaks occurred during the war, when hospital superintendents were experiencing considerable difficulty in maintaining adequate staffs. Whenever decreases in personnel became necessary, there was a tendency to limit the staff in the nursery before reductions were made elsewhere. Frequently, hospital administrators substituted relatively untrained personnel, such as ward attendants and Red Cross aids, for trained persons in the nursery only to regret this practice after serious outbreaks had occurred.

Inadequacies in nursery procedures and formula preparation may be ascertained by technical methods. The hospital bacteriologist can readily determine whether the formulas, nipples, thermometers and other utensils used in the care of newborn infants have been properly sterilized.

It is a frequent misconception that disinfectants by cursory contact kill the bacterial flora on instruments and hands. Actually, many of the ordinary disinfectants kill only after fairly prolonged contact. Furthermore, the killing — or more accurately, the inactivating — effect of certain disinfectants may be reversed even after prolonged contact by the addition of certain substances to the substrate.

Dubos²³ recently pointed out that staphylococci failed to grow after being exposed for a few hours to a bichloride of mercury solution. If, however, the poisoned culture is treated with hydrogen sulfide, the cells recover their viability even though they have been exposed for seventy-two hours to a 1 per cent bichloride of mercury solution. Dubos²³ further points out that the presence of certain materials, such as phosphatides and phospholipids, which are frequently present in biologic materials, may actually protect bacterial cells from the action of the disinfectant.

Moreover, the activity of a disinfectant can be considered, in general, to vary with the concentration, the number of bacteria exposed and the nature of the substrate. It stands to reason that the prolonged use of a given volume of disinfectant results in the accumulation of extraneous materials, such as oils and grease from instruments, desquamated cells from the skin and dead bacteria, that not only reduce the effective concentration of the active disinfectant but also may inactivate it to the extent that bacterial growth occurs. Disinfecting solutions must be fresh and used intelligently if they are to be effective.

It has been shown that so-called "sterilizing solutions" (hand dips) are frequently heavily contaminated. Moreover, 95 per cent ethyl alcohol (with Congo red), used in one nursery as a hand dip, is

seven days of the occurrence of the first case, whereas in 10 cases at least a month elapsed before such notification. In one outbreak there was a span of twenty-nine days between the onset of the first fatal case and the beginning of the outbreak. In two other outbreaks, thirteen and twenty days, respectively, elapsed before the onset of an ultimately fatal case. Long intervals between the onset

practically useless as a disinfectant. It has been known for some time that the alcohols in concentrations of over 50 per cent exhibit little or no disinfecting activity. To cite an extreme case, Koch,²² in 1881, found that spores remained viable for as long as four months when immersed in absolute ethyl alcohol.

The ineffectiveness of these disinfecting solutions was further emphasized by the demonstration that, with the addition of small amounts of protein in the form of nutrient broth, they actually supported bacterial growth (Table 8). Samples of disinfectants

*Constant volume of 1 cc

†Added in form of 1 per cent peptone broth

in current use in various nurseries were collected and filtered through a Seitz filter to remove the accumulated debris and bacteria. Increasing amounts of peptone broth were then added to a fixed volume of disinfectant. Each tube was inoculated with a small particle of stool collected from an infant in the nursery. The amount of stool varied but was always considerably less than that remaining on a rectal thermometer after use. Some solutions, to which as little as 10 mg. of protein had been added, readily supported bacterial growth.

In the outbreaks reported here, *Staph aureus* and various streptococci were encountered frequently from both patients and contacts (Table 8). No etiologic relation is claimed for these micro-organisms, but they may be considered as indicating transmission of an infectious agent from infant to infant or from formula to infant. In several outbreaks the same type of streptococci was isolated from infants and nose and throat cultures of nurses. Nevertheless, no definite conclusions could be drawn concerning either transmission or portal of entry.

In three hospitals, although certain techniques in the nursery were considered inadequate, cultures taken of formulas and equipment did not reveal bacterial contamination. In one of these hospitals infection spread from a nursery to another nursery on the floor above without the interchange of infants, utensils or personnel from one ward to another,

air-borne transmission, or at least indirect transmission other than case-to-case contact, was suggested.

On the other hand, the frequency with which Lancefield Group D streptococci were encountered in the throats of infants with epidemic diarrhea of the newborn suggests infection by the fecal-oral route. Salmonella infection of the newborn is further evidence that where poor techniques are employed, infants may be exposed to organisms often associated with the human intestinal tract.

On several occasions outbreaks started among premature babies and spread subsequently to full-term infants. The increased susceptibility of premature infants is reflected in their higher morbidity and case mortality. Particular attention must be given to premature infants in setting up safeguards against epidemic diarrhea of the newborn.

By utilizing the scoring method evolved in this study, hospitals may evaluate their own nursery procedures and formula preparation. Since there is no definite information concerning the etiology and mode of transmission, it is extremely important that institutions providing care for the newborn should avail themselves of every possible means of preventing epidemic diarrhea of the newborn. It is obvious that closer attention to the details of nursery techniques will lessen considerably the risk of cross infections in hospital nurseries and will serve as a precaution against this extremely serious disease.

SUMMARY

During the interval 1935 to 1945, a total of nineteen outbreaks of epidemic diarrhea of the newborn were reported to the Massachusetts Department of Public Health. Of 768 newborn infants who were exposed during the course of these outbreaks, 258 (33.6 per cent) developed symptoms and 85 died, the case mortality being 33 per cent.

The morbidity rates among premature and full-term infants were 49 and 21 per cent respectively. The case mortality for premature infants was 53 per cent, more than twice that for full-term babies, which was 25 per cent.

Investigation of nursing techniques and methods of formula preparation in nurseries where these outbreaks occurred revealed many inadequacies. Overcrowding, insufficient personnel, general use of a common rectal thermometer and inadequate supervision of formula making were frequently encountered.

Laboratory examinations of so-called "sterilizing solutions," including alcohol hand solution and thermometer dips, formulas, nipples and other utensils showed heavy bacterial contamination.

The ineffectiveness of such disinfecting solutions was further illustrated by experiments demonstrating that with the addition of small amounts of protein they actually supported bacterial growth.

A method is presented by means of which the efficiency of technics used in handling newborn infants may be evaluated

In several outbreaks apparently identical organisms were isolated from sick and healthy infants, nursery personnel and formulas *Staphylococcus aureus*, Lancefield Group D streptococci and Lancefield Group A (Griffith, Type 6) were among the bacterial agents isolated

The presence of Group D streptococci in the throats of infants with epidemic diarrhea of the newborn suggests that, as the result of poor nursery technics, infants may be exposed to organisms that are normally found in the human intestinal tract

Because the etiology and the mode of transmission of epidemic diarrhea of the newborn are not known, supervision of nursery-room technics and of formula preparation constitutes a factor in the hospital care of newborn infants that merits greater attention from hospital administrators

LEIOMYOMA OF THE JEJUNUM*

Report of a Case

SAMUEL F. MARSHALL, M.D.,† AND MARK L. WELCH, M.D.‡

BOSTON

MASSIVE hemorrhage into the gastrointestinal tract is usually associated with a penetrating ulcer of the posterior wall of the duodenum. Serious massive hemorrhage, however, occasionally occurs with the less frequent benign leiomyoma and malignant leiomyosarcoma of the stomach and small intestine. In the case of leiomyoma of the jejunum with massive enterorrhagia and melena reported below, the preoperative diagnosis was bleeding duodenal ulcer.

Leiomyoma of the small intestine is rare. Smith,¹ in 1937, in a review of the literature, was able to collect 513 cases of leiomyomas of the gastrointestinal tract. Of these 50 occurred in the esophagus, 321 in the stomach, 109 in the small intestine and 33 in the colon. In reviewing the records of 36,000 cases at autopsy at the Philadelphia General Hospital, he found 33 cases of gastrointestinal leiomyoma, 8 of which arose in the small bowel. In 1942 Weber and Kirklin² analyzed the material at the Mayo Clinic over a thirty-two-year period and gathered a total of 108 malignant tumors and 41 benign neoplasms of the small intestine. In the latter group, myomas occurred in 14 cases, 8 of these being found in the duodenum, 4 in the jejunum and 2 in the ileum.

Small-bowel leiomyomas are found about equally in both sexes, most frequently between the ages of thirty and forty, but they may occur at any age. One case has been reported in a two-year-old child.³

Small-bowel leiomyomas may be classified according to their location in the bowel wall as primarily of submucosal (inner or intraluminal) or subserosal (outer or extraluminal) origin. The former are small, pedunculated or sessile tumors, usually less than 5 cm. in diameter, that extend into the lumen of the bowel. They are three times as frequent in the jejunum and ileum as in the duodenum.¹ Subserosal leiomyomas are slowly growing, egg-shaped tumors, varying in size from 7 to 30 cm. in diameter. They are usually located on the antimesenteric border of the bowel and extend into the peritoneal cavity. They occur almost twice as frequently as the submucosal type and are often found unexpectedly at laparotomy or autopsy.¹

Malignant change is surprisingly frequent in leiomyomas of the small intestine, being reported in 15 to 20 per cent of cases.⁴ Subserosal leiomyomas

are particularly prone to become malignant, metastases or recurrences having taken place in 16 per cent of the reported cases.¹ No metastases or recurrences have been reported in tumors of the submucosal variety.

Not all leiomyomas of the small bowel give rise to symptoms. In Raiford's⁵ series 46 per cent were incidental findings at necropsy. The submucosal variety, however, is rarely asymptomatic, regardless of size. The clinical manifestations, which are variable and depend on the location, size and character of the tumor, are predominantly those of intestinal obstruction and enterorrhagia. Submucosal leiomyomas of the duodenum often cause partial obstruction and ulcerlike pain, when they are located below the ligament of Treitz, intussusception is the usual result. Repeated attacks of intestinal obstruction secondary to intussusception are the most frequent clinical findings, occurring in 62 per cent of the collected cases.¹ Superficial ulceration of the tumor results in enterorrhagia and melena, repeated attacks being not unusual. Subserosal leiomyomas may reach such size as to attract the patient's attention and may, by mechanical stress, produce partial intestinal obstruction, but as a rule they tend to be asymptomatic. Occasionally, progressive central necrosis in the tumor occurs, with evacuation into the intestinal tract, producing a pseudodiverticulum from which severe enterorrhagia is likely to continue until death unless operation is performed. The principal clinical manifestations are gastrointestinal hemorrhage and melena, which occur in 31 per cent of cases.

Less frequent clinical findings in leiomyoma of the small intestine are peritoneal irritation, secondary to necrosis of the tumor or volvulus, and frank peritonitis due to rupture.

Usually the diagnosis of jejunoileal leiomyoma is made at operation or autopsy. As in the case reported below and in others, the preoperative diagnosis is usually bleeding duodenal ulcer or intestinal obstruction, the etiology being undetermined. Ordinary barium study of the gastrointestinal tract may reveal a defect caused by a duodenal myoma, but below the ligament of Treitz it is rarely useful in the diagnosis of these tumors. The most accurate method of detecting a jejunoileal lesion is by serial roentgenograms taken every hour for five hours following a barium meal.⁶ If obstruction resulting from a tumor of the small bowel is present, a roentgenogram of the abdomen will reveal the usual evidence of dynamic ileus.

CASE REPORT

A 53-year-old widowed schoolteacher was first seen in the Lahey Clinic on October 15, 1943, complaining of epigastric distress, tarry stools and fainting of 4 weeks' duration. She had been in good health until 1941, when for about 6 months, she had gaseous indigestion and epigastric distress. This discomfort occurred daily about 2 or 3 hours after meals, and was partially relieved by food or soda. There was no vomiting, hematemesis or melena. Appendectomy had been done in July of that year, with relief of symptoms except for an occasional mild attack of gaseous indigestion. The patient had remained quite well until 1 month before admission, when at 2 o'clock in the morning, she was awakened by a "dull pressing ache" in the epigastrium, which seemed to push upward against the diaphragm and chest. There was nausea but no vomiting. The discomfort was relieved somewhat by bicarbonate of soda and she was able to sleep the remainder of the night. She awoke at the usual time, had breakfast and went about her work. In about 2 hours she was seized with a similar attack of epigastric discomfort, became weak and was nauseated but did not vomit. An almost constant desire to defecate was present. After a soft, tarry stool, she fainted and was unconscious for about 2 minutes. She was taken home and put to bed but continued to have repeated, loose, tarry stools. After about 10 days of bed rest and treatment by a physician, the bleeding subsided. Following roentgenologic studies of the gastrointestinal tract on September 27, the presence of a "filling defect of the duodenopyloric region not typical of ulcer" was reported. The physician referred the patient to this clinic for further study.

Physical examination was negative except for moderate tenderness to the left of the midline in the upper abdomen. The blood pressure was 132/76, and the pulse 76. Rectal examination was negative. Examination of the blood showed a red-cell count of 4,100,000, with a hemoglobin of 9.9 gm., and a white-cell count of 5400, with normal differential and platelet counts. Gastric analysis revealed 10 units of free acid and 40 units of total acid. Barium studies of the gastrointestinal tract were negative. Although a lesion of the gastrointestinal tract could not be demonstrated by roentgenologic examination, a clinical diagnosis of duodenal ulcer with recent hemorrhage was made. An ambulatory regimen for ulcer, consisting of a strict diet and antacids, was instituted. The patient was seen at the clinic at regular intervals and, except for mild and transient episodes of epigastric distress, did well for more than 18 months. On April 2, 1945, following the eating of apple pie, she again had a severe attack of epigastric distress, followed by melena.

Physical examination on April 12 was negative. The blood pressure was 150/83, and the pulse 70. Examination of the blood showed a red-cell count of 4,200,000, with a hemoglobin of 11.8 gm. The sedimentation rate was normal. Gastric analysis showed 20 units of free acid and 61 units of total acid. Barium studies of the gastrointestinal tract revealed a persisting indentation at the peak of the duodenal cap, which was present both on fluoroscopy and in the films. The patient was again placed on a strict ulcer regimen. She was co-operative, followed instructions well and did satisfactorily until March 23, 1946, when melena again occurred. Hemorrhage was profuse, with repeated tarry stools, necessitating hospitalization.

On March 30 the patient was admitted to the hospital on the gastrointestinal service. Examination disclosed an apprehensive patient whose skin and mucous membranes were somewhat pale. The blood pressure was 118/62, and the pulse 112. Abdominal examination revealed no abnormalities. Examination of the blood disclosed a red-cell count of 1,950,000, with a hemoglobin of 5.6 gm., and a white-cell count of 8500. The hematocrit reading was 18 per cent. During the four days following admission melena continued and, despite medical treatment, including repeated daily transfusions of whole blood and plasma, could not be controlled. The red-cell count could not be elevated above 2,500,000 or the hemoglobin above 7 gm. A diagnosis of bleeding duodenal ulcer was made by members of the gastroenterology service, who believed that operation would be necessary to control the hemorrhage. The surgical consultant agreed, and operation was arranged.

Celiotomy was performed on April 5 under fractocoll pontocaine spinal anesthesia, with supplemental cyclopropane anesthesia. The stomach and duodenum were found to be entirely normal. The first, second and third portions of the duodenum were carefully visualized and palpated, but no abnormalities could be found. There was no evidence of an old or recent ulcer. The liver was normal, and there was no indication of dilated veins or varices about the cardiac end of the stomach or the esophagus. In the jejunum, approximately 15 cm from the ligament of Treitz, a polypoid tumor was palpated, it was quite firm, measured approximately 3 cm in diameter and appeared to involve both the serosa and the mucosa. There were a few slightly enlarged lymph nodes in the mesentery adjacent to the tumor. Distal to the tumor but not proximal to it, the small and large bowels were filled with blood. It was decided that the tumor was responsible for the hemorrhage, and a segmental resection of the jejunum with open end-to-end anastomosis was done.

Pathological examination was performed on a specimen consisting of small intestine measuring 90 x 70 x 0.8 cm. The serosal surface was smooth and shiny, with a central rounded protrusion rising 0.3 cm above the surface. In the center of the mucosal surface there was a previously opened, rounded, papilliform projection measuring 2 cm in length, 1.5 cm transversely and 2.5 cm in longitudinal diameter. It was covered by mucosa and had a firm, rubbery base, measuring 1.5 cm in diameter. The cut surface showed a granular mottled, grayish pink and red surface. The microscopic diagnosis was leiomyoma of the jejunum.

This case, as in the usual tumor of the small bowel, was incorrectly diagnosed as duodenal ulcer. Fortunately, celiotomy was performed, the source of the hemorrhage was found and the patient completely recovered. Fatal cases of suspected bleeding duodenal ulcer have been reported in which operation was withheld and autopsy disclosed a bleeding benign neoplasm of the small bowel.^{1, 2, 3, 7} When there is continued melena and inability to control shock and hemorrhage through conservative measures of rest, morphine and restoration of blood volume by repeated transfusions, surgical interference is imperative if death is to be avoided.

Roentgenologically, the small intestine is said to be the blind spot of the abdomen. The key to the diagnosis of small-bowel lesions is suspicion. A patient who has persistent atypical ulcer pain, recurrent episodes of melena or repeated attacks of small-bowel obstruction without a demonstrable lesion of the gastrointestinal tract should be suspected of having a small-bowel neoplasm. If such a lesion is suspected by the clinician and the roentgenologist so advised, special studies often reveal the tumor.

* * *

The incidence, pathologic characteristics and clinical manifestations of leiomyoma of the small intestine are reviewed.

A case of leiomyoma of the jejunum is reported in which the preoperative diagnosis was incorrect but the treatment was successful.

This case emphasizes the fact that the presence of small intestinal neoplasms is much too infrequently suspected.

ARTHROPLASTY OF THE ELBOW*

W RUSSELL MACAUSLAND, M D †

BOSTON

FOR nearly forty years ankylosed elbows have been reconstructed by arthroplastic procedures consisting of reshaping the articular ends and interposing a flap of fascia for a gliding surface. In 1908, I performed one of the first arthroplasties of the elbow using free fascia as the interposing membrane. With increased experience in the use of the method, which led to improvement in the operative technic and better judgment in the selection of cases, the results of arthroplasty of the elbow have come to be almost routinely satisfactory.

The reconstruction of a joint by arthroplasty is not a simple procedure. A new joint must be created that not only has a functional range of motion but is also stable and well controlled. For the elbow to be useful, the motion must range from at least 45° of flexion to 170° of extension. Stability is a factor that is quite as important in the mobilization of the non-weight-bearing elbow joint as in the reconstruction of hip and knee joints. It is of no advantage to a patient to obtain a movable joint if at the same time it is abnormally mobile, unbalanced and not under control.

Not every ankylosed elbow is suitable for arthroplasty. The origin of the stiffness must first be considered. Cases of purely traumatic origin lend themselves best to arthroplasty. Good results may be obtained in cases of ankylosis of pyogenic infectious origin, provided that the disease is not progressive and provided that it is quiescent. Arthroplasty cannot be carried out with safety until at least a year has elapsed from the time of the disappearance of all signs of the disease. Among cases of infectious origin, those of gonorrheal invasion offer the best chance of a successful outcome. Mobilizing measures in cases of tuberculous involvement can be carried out only in exceptional cases, on the whole, arthroplasty is considered to be contraindicated in such cases.

The ages at which arthroplasty is performed most successfully are between nineteen and forty-five years. The procedure may be considered when the patient is fifty years of age, provided the bone and musculature are in good condition. Operative inter-

vention at an earlier age than nineteen may cause damage that will interfere with growth.

Bone, musculature and skin must be in good condition. It is difficult to remodel the articular ends in the presence of eburnated bone or extreme bone atrophy. The muscles controlling the joint should be free from scar tissue and in good tone, so that the aftercare will be in no way retarded. When the skin or subcutaneous tissue is adherent to bone, the operation is difficult. If it is not possible to restore the bone, musculature and skin to good condition, the ultimate success of arthroplasty is questionable, and the operation is, as a rule, contraindicated.

Finally, the general health and mental outlook of the patient must be considered. An important pre-operative step is the careful checking of all possible foci of infection. The more co-operative the patient is in withstanding the convalescence and in carrying out the postoperative treatment to establish motion, the greater are the chances of success.

Operative Technic

The elbow joint is approached by a semicircular incision that curves over the olecranon and extends from one condyle to the other (Fig 1). The skin and subcutaneous tissues are dissected, and the flap is retracted. The ulnar nerve is retracted to the ulnar side. A transverse incision is made through the deep fascia, ligaments and capsule down to the periosteum. The olecranon is chiseled through transversely at the joint line.

The joint is then ready to be broken open. This step is more easily carried out when the joint line is still visible and the joint surfaces can be separated by means of curved chisels (Fig 1). When the joint cavity is entirely obliterated in a bony bridge, the site of the old joint line is determined as closely as possible and then chiseled or sawed through. The forearm is flexed, the olecranon segment freed, and the flap dissected back in toto. This flap is preserved for a subsequent covering of the joint.

In the remodeling of the articular surfaces, the normal contours of the joint are followed as closely as possible. The articular ends should fit together accurately. Care should be taken to remove only enough bone to permit free motion. An electric burr

aid in maintaining the lateral stability of the joint. It may be necessary to deepen the radial and ulnar surfaces somewhat with an electric burr, so that they will conform to the humeral surfaces. The ulnar

chromic catgut is wound tightly around the base of the fascial flap and firmly tied.

The articular ends are brought into apposition. A screw is driven through the olecranon and into the

FIGURE 2 *Technic of Operation*

These sketches show the remodeling of the humeral condyles with an electric burr and the cutting of the fascia lata from the thigh

ridge, which articulates with the intercondylar notch, should not be disturbed.

A flap of fascia lata is removed from the outer part of the thigh (Fig 2). After the flap has been

ulna (Fig 3). The capsule is closed with interrupted sutures of catgut, and the skin is closed with interrupted sutures of silk. A small compression dressing is applied. The arm is immobilized in a neck and

wrist sling, with the forearm flexed just above the right angle

The postoperative treatment is an essential part of the arthroplastic procedure, and the success of the operation depends to a great extent on the cooperation of the patient in this aftercare. The pa-

many of these cases are to be found in the literature¹⁻⁴. Our results have proved that the elbow lends itself well to arthroplastic measures. The results have been excellent, the patients obtaining both a satisfactory range of motion and a joint that is stable and well controlled. No arthritic changes have de-

FIGURE 3. *Technic of Operation*

These sketches show the sewing of the flap of fascia lata to the capsule anteriorly, the fascial flap in place over the humeral condyles and the screw through the olecranon

atient should practice contraction exercises of the arm and forearm muscles hourly, to maintain their tone and to improve the circulation. The dressing is changed in a week. Passive motions are carried out in about ten days after the operation. Gentle massage may be given in three weeks. The patient also begins to use the arm after the third week, returning it to the sling only for rest.

* * *

More than 100 ankylosed elbows have been mobilized by arthroplasty in our clinic. Reports of

veloped in later years, even in the joints of men working in heavy industries.

THE EFFECT OF AMPHETAMINE SULFATE ON SPASMODIC FLEXION MOVEMENTS OF THE FOOT*

Report of a Case

JULIUS LOMAN, M.D.†

BOSTON

DISTURBANCES in tone and motion of voluntary muscles,—including rigidity, hyper-tonicity, dystonia, rhythmic or oscillating tremor, athetosis, choreiform movements and spasmodic or torsion movements,—present either singly or in combination, usually indicate dysfunction of the extrapyramidal pathway. These symptoms are sometimes so bizarre that they may be mistaken for manifestations of hysteria. The peculiar disorder presented by a striking case recently observed falls

ganglions. In the most frequent disease of the extrapyramidal pathway, Parkinson's syndrome, amphetamine (Benzedrine) sulfate, if given in sufficient dosage (20 mg or more), often diminishes the rigidity but has little if any influence on the tremor.¹ In some cases of spasmodic torticollis the drug is beneficial.² In my experience little or no benefit results from the use of amphetamine sulfate in dystonia athetosis, dystonia musculorum deformans or familial tremor of the head. It is my practice to

FIGURE 1 Photograph Showing the Spasmodic Hyperflexion of the Toes of the Left Foot

into this category. A spasmodic flexion of the toes was the presenting symptom. The successful relief of the condition by medication prompted the presentation of the case reported below.

Medication is often ineffective or unsatisfactory in the treatment of most of the muscular spasms and rigidities associated with disorders of the basal

ganglia. In the most frequent disease of the extrapyramidal pathway, Parkinson's syndrome, amphetamine (Benzedrine) sulfate, if given in sufficient dosage (20 mg or more), often diminishes the rigidity but has little if any influence on the tremor.¹ In some cases of spasmodic torticollis the drug is beneficial.² In my experience little or no benefit results from the use of amphetamine sulfate in dystonia athetosis, dystonia musculorum deformans or familial tremor of the head. It is my practice to

*From the Department of Neurology, Beth Israel Hospital.
†Assistant professor of neurology, Tufts College Medical School, chief of Department of Neurology and Out Patient Department Clinic in Neurology, Beth Israel Hospital.

F. J., a 20-year-old boy, was seen at the Out-Patient Department, Beth Israel Hospital, on March 3, 1942. There was no familial history of any neurologic disorder. The patient had had the usual childhood diseases, including mumps,

asles and scarlet fever. There had been no illnesses suggestive of encephalitis. In 1932 a large boulder weighing out 15 to 20 pounds was dropped on the left foot producing bruises and causing a limp for several days, but there were other ill effects. The patient had had jaundice in 1938. In 1939 he noted that the toes of the left foot flexed voluntarily, particularly while he was walking. This symptom was associated with a tired and tight feeling in the left leg and the thigh muscles. The involuntary movements of the foot gradually increased in severity and became continuous so that walking for more than a short distance became impossible. The patient had to discontinue work because of this disability.

Neurologic examination was negative except for the left foot. When the patient was in a standing position, the left toes were held in a state of marked hyperflexion so that the toenails — except that of the great toe — were completely hidden from view (Fig 1). Frequent slow spasmodic movements of the toes were present. Active extension of the toes was practically impossible, and passive extension was performed with difficulty. There was increased tone in the calf and thigh muscles. Walking was attended by great discomfort. All the deep reflexes were equal and lively, the left knee jerk being probably more active than the right. There was no Babinski reflex or ankle clonus. The sensory examination was normal. The cranial nerves were intact.

Examination of the spinal fluid disclosed clear fluid with an initial pressure equivalent to 95 mm. of water and normal dynamics. There were no cells. The total protein was 42 mg., the chloride 776 mg. and the sugar 96 mg. per 100 cc. The old-sol curve was 0000000000. Spinal-fluid Hinton and Kahn tests were negative. An x-ray film of the skull was normal.

The patient was given 30 mg. of amphetamine sulfate by intramuscular injection. Within $\frac{1}{2}$ hour a marked improvement in the muscular symptoms of the foot and leg occurred. The flexion spasm of the toes practically disappeared so that the patient was able to extend the phalanges almost completely. There was marked increased speed of movements of the toes. Walking became almost normal. The tightness in the leg and thigh disappeared. These effects of the drug gradually wore off over a period of 3 or 4 hours, with a return of the symptoms to their previous level. On the following day, to exclude the factor of suggestion, the patient was given an intramuscular injection of normal saline solution, which had no effect on the symptoms of the foot. Amphetamine sulfate

was then administered orally, in a dose of 20 mg. twice daily. To each 20 mg. of the drug, 30 mg. of phenobarbital was added, the latter sedative was also given at night to counteract the sleep-disturbing effect of the amphetamine sulfate.

On this medication marked improvement of the muscular symptoms has been maintained for forty-five months, so that the patient is able to walk long distances with little discomfort. There is an almost complete disappearance of the flexion spasm of the toes and of the feeling of tightness in the leg muscles. A residual mild hyperflexion of the toes remains. Omission of the amphetamine sulfate invariably results in recurrence of the symptoms to their previous level.

* * *

A case of spasmodic flexion movements of the toes is reported. This condition responded satisfactorily over a period of forty-five months to the oral administration of amphetamine (Benzedrine) sulfate.

It is recommended that patients who present symptoms suggestive of basal-ganglion origin be given an intramuscular dose (20 to 30 mg.) of amphetamine sulfate. If the symptom is beneficially influenced within approximately twenty minutes, the drug may then be taken orally in effective doses. Phenobarbital or another similar sedative may be prescribed with the amphetamine sulfate to counteract central overstimulation and may also be given at night to prevent the sleep-disturbing action of the latter drug.

MEDICAL PROGRESS

OBSTETRICS

BENJAMIN TENNEY, JR., M.D.*

BOSTON

THE following survey of the recent literature concerns significant developments in the management of various problems of obstetric practice

HABITUAL ABORTION

Habitual abortion continues to be one of the important problems facing the obstetrician. The study of the endocrine factors involved has offered a new approach of considerable value. Real progress has been made during the past year, with the result that a successful outcome can be obtained in certain pregnancies that would otherwise end in disaster.

All patients giving a history of two or more abortions should be thoroughly investigated. Thyroid deficiency, a frequent cause, should be checked by a test of the basal metabolic rate. General systemic disease should be ruled out. Pelvic tumors and other diseases should also be excluded. The general health of the husband, as well as the viability and morphology of the sperm, must be checked. If any abnormality is found in either partner, further investigation and treatment are indicated.

There are a large group of patients in whom no definite cause for abortion can be demonstrated. These patients may have normal fertility and yet may not be able to carry a pregnancy beyond two or three months. Among other attempts at treatment in these cases, many hormones have been tried, with little success. Progesterone, in particular, has proved a disappointment in most cases. Recently, a more scientific and hopeful approach has been made.

Vaux and Rakoff¹ have shown that a high percentage of habitual aborters exhibit a low pregnanediol titer and, even more frequently, diminished blood and urine estrogen levels. These findings indicate a hypofunction of the endocrine glands of pregnancy that may be due to the failure of the corpus luteum or the placenta. These authors have tried replacement therapy in a series of cases, with reported success. Their patients received 10 mg of progesterone and 10,000 rat units of alpha-estradiol benzoate two or three times weekly. The results are far more encouraging than those with progesterone alone.

Smith, Smith and Hurwitz² state that there is a low excretion of pregnanediol in patients experienc-

ing premature deliveries and intrauterine deaths. They have found the hormone titers in early pregnancy to be too varied to state a normal level. They were able, however, to cause a marked increase in the excretion of pregnanediol by the administration of large doses of diethylstilbestrol. Starting at the sixteenth week of pregnancy, with 30 mg of stilbestrol daily, they increase their dosage 5 mg weekly until a maximum of 125 mg a day is reached. This does appear to be a large dose, but it has been shown clinically that pregnant women tolerate stilbestrol much better than nonpregnant.

On the basis of this work, similar doses of the estrogens have been given, early in pregnancy, to habitual aborters. It was believed that since the estrogens increased the output of progesterone in the pregnant woman, progesterone need not be given. In many cases the stilbestrol was started before conception so that the pregnancy might begin with the proper hormone balance. Smith³ states that although this may prove to be the proper procedure, it may confuse the diagnosis of pregnancy, under this treatment patients will show an enlargement of the uterus, breast changes and other signs of pregnancy. Also, the therapy may cause a false-negative pregnancy test. Clinical results have been most encouraging, indicating a real improvement in the treatment of habitual abortion.

Hertig and Livingstone⁴ report on the pathological examination of 1000 cases of abortion. In this series the ova were anatomically normal in 26.6 per cent of cases. Considering all types of abortion, in which the fetus was otherwise normal, at the time of abortion, it is apparent from these figures that the pregnancy was essentially normal in 49.9 per cent of cases when the signs or symptoms brought the patient to the physician. From these figures it seems that the fetus in approximately half of all abortions has a possibility of being saved with proper treatment.

THE RH FACTOR

Among the recent developments in medicine, the Rh factor has become particularly important in the field of obstetrics. This factor is an antigen that, for all practical purposes, may be considered entirely similar to the A and B substances also found in the red cells. The Rh factor is present in about 87 per cent of white people, according to Diamond.⁵ It is the absence of this factor that is of significance

*Associate professor of obstetrics, Boston University School of Medicine; assistant visiting surgeon in obstetrics and gynecology, Boston City Hospital; assistant obstetrician, Massachusetts General Hospital.

Transfusion of Rh+ blood into an Rh— woman may cause an increasing hemolytic reaction, with the formation of antibodies. The factor exists only in red cells, and no anti-Rh antibody normally exists in human serum.

A woman with Rh— blood married to a man with Rh+ blood may have a fetus with Rh+ blood. In about one of fifteen such cases, the mother may be sensitized by one or more pregnancies. Once so immunized, the woman cannot be given a transfusion of Rh+ blood without danger of a fatal reaction. A single Rh+ transfusion to a non-pregnant woman with Rh— blood may initiate an antibody response. A subsequent pregnancy may cause erythroblastosis in the child.

In the pregnancy of an Rh— woman carrying an Rh+ fetus with an Rh+ father, the mingling of fetal and maternal blood is at first unimportant. In fact, since there is no direct mixing of the two bloods, some leakage must take place. During the first pregnancy, there is such slight admission of fetal red cells to the maternal system that only a small amount of antibody is formed. As a result, the first child is generally born in good health. The antibodies set up by the first pregnancy are retained by the mother and added to in succeeding pregnancies. In the second or third pregnancy the antibodies may reach sufficient concentration to enter the fetal blood and set up a hemolytic reaction. This may result in erythroblastosis in the fetus.

From a clinical point of view, it is essential that a careful history be taken on all pregnant women, first regarding blood transfusions and secondly concerning the presence of jaundice, anemia or stillbirth in any previous children. Should a positive answer be obtained to any of these questions, it is imperative that blood typing for the Rh factor be done. If the woman is found to be Rh— a further search for the presence of antibodies should be made.

It is also generally believed that all pregnant women should be typed for the Rh factor, even if they have had one or more normal children previously. If they are Rh— they may have been building up antibodies during the earlier pregnancies. Should the woman be found to have Rh— blood, a test for antibodies should be made about the twentieth week of pregnancy. If the test shows sufficient antibodies, labor should be induced as soon as possible, from the point of view of the safety of the infant. If the infant shows any sign of anemia or jaundice, a blood smear should be examined for evidence of erythroblastosis. If positive, a transfusion of Rh— blood should be given.

Blood of jaundiced infants of untyped mothers should be examined for evidence of erythroblastosis, and if the smear is positive, the infant should be given a transfusion of Rh— blood. Blood from the mother should not be used for transfusion to the child.

It is equally essential that an Rh— mother receive Rh— blood should a transfusion be necessary. This is important both from the danger of a transfusion reaction and from the danger of building up antibodies that might endanger the fetus in a future pregnancy.

Bouton⁶ states that Rh— mothers with antibodies in their blood should not nurse their children, since the antibodies may pass to the child through the mother's milk.

HEMORRHAGE

In the statistics of maternal deaths, a general improvement is apparent except in death from hemorrhage, indicating that sufficient advantage is not being taken of the greatly improved availability and simplicity of blood transfusion. It is also evidence that loss of blood during pregnancy, labor and post partum is not sufficiently checked. Too often, such observation is left in the hands of nurses or interns. Blood loss in obstetrics is difficult to judge. An experienced observer is necessary. This is the responsibility of the attending obstetrician and should not be delegated to others.

Gordon,⁷ in an excellent review of the causes of maternal death in Brooklyn, brings out the fact that in death reports the proper relation of hemorrhage to the cause of death is frequently omitted. He states that maternal death is often due to several causes rather than a specific one. In many cases of death from sepsis, the patient's resistance to infection has been severely damaged by excessive blood loss. There are other cases, such as cardiac failure, in which the final cause of death was precipitated by hemorrhage. Gordon reports that in Brooklyn, in 1943, a careful review of the maternal deaths showed that in 53 per cent hemorrhage was a significant factor. There were more deaths from hemorrhage than from any other cause, including toxemia and sepsis. It appears that the control and treatment of hemorrhage offer the greatest opportunity for a decline of the maternal death rate. Certainly, in many cases of death from hemorrhage, the patient could have been saved if the condition had been recognized early and proper treatment given.

Greenhill⁸ gives the following instructions for all women who bleed during the last few months of pregnancy. They should be sent to the hospital at once, without examination at home and without packing, except on rare occasions. They should be moved in an ambulance. On arrival at the hospital, determinations of blood type and Rh factor should be made immediately, if they have not been done previously. No rectal examinations should be performed. No vaginal examination should be done until the patient is in the delivery room, with sterile equipment for control of hemorrhage and rupturing the membranes. Further safety can be obtained by having the operating room set up for a laparotomy.

in case the vaginal examination starts free bleeding from a central placenta previa or other uncontrollable cause

The treatment of placenta previa is cesarean section in severe cases. In some cases of marginal previa in which the bleeding can be controlled by rupture of the membranes, the patient can be safely delivered from below. The use of a bag in this condition has largely been discarded. Williamson and Greely,⁹ in a description of a series of 162 cases from the New York Hospital, stress the fact that the operating room should be ready before examination. Central previa should always be treated by cesarean section. The best results were obtained from vaginal delivery when the bleeding could be controlled by rupture of the membranes. In a report of a ten-year study at the Sloan Hospital, Watson¹⁰ describes a maternal mortality of 11.5 per cent with the use of a bag against a maternal mortality of 3.4 per cent in cesarean section. The fetal mortality was 50 per cent with the use of a bag, and 4 per cent in cesarean section. With rupture of the membranes, the fetal mortality was considerably higher — 17 per cent — than with cesarean section. Watson also mentions some degree of shock in 63 per cent with the use of the bag.

In the treatment of abruptio placenta, conservative treatment or cesarean section may be employed. There is some difference of opinion in this matter. Gustafson¹¹ emphasizes the availability and use of large amounts of blood and plasma in these cases. He considers the ideal case for cesarean section to be an abruptio placenta of moderate degree, with the patient not in labor, or with labor not advanced, and with the fetal heart tones audible. In severe cases with a dead fetus, conservative treatment is often preferred. Conservative treatment includes rupture of the membranes, with small doses of pituitary extract to stimulate labor. Vaginal packing has not proved successful in controlling hemorrhage and is not in general use. The Spanish windlass is in the same category. Supportive treatment of the patient, including whole-blood transfusions, is extremely important. In many cases, even those with a dead fetus, if the cervix is hard and undilated, a cesarean section may be the preferable procedure. In any case of premature separation of the placenta, delivery from below may be followed by hysterectomy for hemorrhage. In the choice of procedure, as in all other types of hemorrhage, the therapy should involve the least possible shock to the patient and the best of supportive treatment, mainly the use of sufficient whole blood.

Rupture of the uterus is an obstetric emergency in which immediate diagnosis is imperative. The keeping of this possibility in mind is essential in diagnosis. Any patient with a previous cesarean section is in danger of rupture of the uterus. Lynch,¹² in a report from the Boston City Hospital on this problem, states that the prognosis is definitely influenced by the amount of time between rupture

and treatment. He considers most cases preventable, since they are due to either operative procedures or oxytocic drugs. He reports rupture following cesarean section as frequent and dangerous. All patients who have had previous sections should be carefully watched during the last few weeks of pregnancy. There is only one treatment for rupture — immediate hysterectomy. Large amounts of blood should be given freely. In patients who have had an internal version or a hard operative delivery from below, any sign of shock or internal bleeding should suggest rupture of the uterus.

In the treatment of obstetric hemorrhage, no one factor is of such help in improving results as the presence of a hospital blood bank. A great deal of time is saved. Also, if blood is easily available, it will be given in more cases. A description of the excellent blood bank at the Boston Lying-in Hospital is given by Irving.¹³

SEPSIS

Sepsis continues to be one of the important causes of maternal death, although statistics are improving. A large part of the present improvement must be attributed to new drugs. In spite of chemotherapy, however, women continue to have sepsis and continue to die from it. There is no reason for an increased confidence or feeling of safety in the attempt to eliminate the causes of sepsis. Much sepsis can be avoided and is due to factors that are preventable.

Septic abortion is, in the great majority of cases, due to artificial interruption of pregnancy. Poor asepsis, poor methods and unskilled hands are largely responsible. Self-induced abortion contributes a large number of these cases. In conjunction with the infection, there is usually considerable blood loss owing to incomplete emptying of the uterus. Also, the delay of patients in reporting to the hospital increases the risk. Many women wait at home until they are seriously ill before being seen. The treatment in these cases should be primarily conservative. When these patients are examined, any tissue protruding from the cervix may be removed, but the uterus should not be entered. Curettage should never be performed except for excessive hemorrhage. Since these patients have generally lost considerable blood, transfusions of whole blood should be given freely. Chemotherapy should be started in large doses. Fifty thousand units of penicillin every three or four hours up to 1,000,000 to 2,000,000 units is necessary. In my experience with 50 severely infected patients at the United States Naval Hospital in San Diego, none died under this regime. Five patients were curetted for hemorrhage, the remainder recovered without surgical interference. In the majority of cases the temperature fell to normal within forty-eight hours. Large amounts of blood were used in this series, no patient receiving less than one and some as many as six whole-blood transfusions.

Puerperal sepsis is well discussed by Douglas and Davis¹⁴ from the New York Hospital in a study of 600 patients with puerperal infection. Hemolytic streptococci were cultured in 90 per cent and aerobic streptococci were present in 70 per cent of their cases. Twenty-five per cent of the blood cultures from the operative deliveries in this series were positive, whereas cultures in only 8.5 per cent of the spontaneous deliveries were positive. Prophylaxis is most important in avoiding infection, careful asepsis in the delivery room being a prime factor. Patients should be watched carefully throughout pregnancy for anemia, since those with anemia have poor resistance to infection. Care should be taken during delivery and the third stage of labor to avoid any excessive loss of blood. Should excessive blood be lost, immediate replacement is indicated. Prolonged labor is a frequent cause of infection, and the increasing risk of infection in such cases should be well realized. Excessive trauma is one of the most avoidable causes of sepsis. Difficult deliveries, such as those by hard forceps and internal version, are fully as dangerous, from this point of view, as laparotomy, and because they often involve blood loss and shock, they should not be undertaken without consideration of these factors. In the application of forceps, skill and gentleness are essential, to avoid damage to the patient. Cesarean section should be done early before a patient is infected. Never should intraperitoneal section be attempted in the neglected or infected case, if delivery from below has been attempted, cesarean section is contraindicated. Avoidance of intercurrent disease is most important.

Douglas and Davis¹⁴ suggest the administration of sulfadiazine prophylactically during a prolonged labor as being of possible value in difficult operative deliveries but do not advise its use routinely.

The treatment of sepsis resolves itself into the primary factors of blood, fluids, nutrition and rest, all of which are of great importance. Sulfadiazine is of definite help in hemolytic-streptococcus and colon-bacillus infections. With the exception of colon-bacillus infection, penicillin is probably of more value. Whichever drug is used, treatment should begin early, with large doses, and should be continued for a sufficient length of time to be effective.

CESAREAN SECTION

Cesarean section continues to hold the attention of many writers. The problem of indications are widely discussed. Reviews of many cases continue to show the results of use and misuse of this operation.

Irving¹⁵ has published the results of ten years' experience with cesarean section at the Boston Lying-in Hospital in a series of 1887 cases, the incidence of cesarean section is given as 4.2 per cent, being twice as high among private patients as among those on the ward service. Operation was performed for dystocia in 71.6 per cent, for hemor-

rhage in 16.6 per cent and for other causes in 11.8 per cent. Irving states that midforceps delivery has proved as dangerous for the mother and eight times as dangerous for the fetus as cesarean section.

Pelvic delivery after a previous section was rarely done on the private service. Irving gives the following requisites for this procedure: the operation must have been done for a temporary indication, such as placenta previa, convalescence must have been afebrile, the procedure must have been performed by a competent surgeon, and after delivery from below the uterus must be explored for possible rupture. Following cesarean section, 78 women were delivered from below without rupture.

In the majority of cases of placenta previa the patients were delivered by cesarean section. Most cases of premature separation of the placenta were delivered by the pelvic route, particularly in the ablatio type. In only one eighth of the cases in which a diagnosis of premature separation was made were the patients delivered by cesarean section.

There was no difference in morbidity between the classic and the low-segment operation. The total morbidity for the series was 21.1 per cent, the total fetal mortality was 6.8 per cent, and the total maternal mortality was 1.3 per cent. There were 1 fatal case of peritonitis, 2 of hemorrhage and 3 of embolism. In all cases diagnosed as toxemia of pregnancy 2.7 per cent of patients were delivered by cesarean section.

Dieckman¹⁶ of the Chicago Lying-in Hospital, reports that statistics show that cesarean section can be performed with a mortality of 1 or 2 per cent in general hospitals and of 0.5 to 1 per cent in maternity hospitals. It is difficult to believe that the mortality must remain twice as high in general hospitals. Is this due to the presence of more intercurrent infection in general hospitals or to less well trained operators than in maternity hospitals? In 1922 the deaths after cesarean section were due to sepsis in 30 per cent, to shock and hemorrhage in 30 per cent and to toxemia in 19 per cent. Half to two thirds of these deaths were preventable. In 1931 five maternity hospitals performed cesarean sections in 6335 cases, with an uncorrected average mortality of 1.46 per cent. Realization of death from sepsis has prompted many obstetricians to an earlier use of cesarean section while the patient is still uninfected. This has caused some increase in incidence in the use of the operation but an absolute decrease in mortality.

Dieckman¹⁶ gives the following indications for cesarean section: obstructing tumors, contracted pelvis, with a true conjugate diameter of less than 8 cm and a transverse diameter of the outlet of less than 7 cm, a test of labor of twelve to eighteen hours in questionable cases being indicated — the pains should occur every two to five minutes, with a maximum of two rectal and two sterile vaginal examinations and with a deadline of twenty-four

hours for rupture of the membranes or labor, repeated cesarean section—a scar of the lower uterus is less apt to rupture than one from a classic section, but in view of the high maternal and fetal mortality from uterine rupture and the impossibility of knowing which scars will rupture, a previous section, in general, warrants a repeat operation, placenta previa, breech position in elderly primiparas or in patients with a contracted pelvis, transverse presentation in primiparas and recurrent transverse presentation in multiparas, and previous plastic operations

Dieckman¹⁶ considers cesarean section indicated in cases with an abruptio placenta with evidence of deep shock, low hemoglobin, a rapid pulse and an enlarged uterus or when dilatation of the cervix does not occur after the membranes have been ruptured for six to twelve hours

Free¹⁷ reports that cesarean section was performed in 500 consecutive cases at the Chicago Lying-in Hospital—an incidence of 4.43 per cent. There were 2 fatal cases, giving a mortality of 0.4 per cent, one death was due to cerebral hemorrhage or eclampsia, or both, and the other to hemorrhage and shock after a central placenta previa. The maternal morbidity, which was 31 per cent, definitely increased with the length of labor and with the rupture of the membranes

Waters¹⁸ recommends the use of extraperitoneal section in all infected and potentially infected patients. He reports extraperitoneal section in 250 cases, with maternal deaths in 2. Many of the operations were done for potential as well as for frank infection

There is no question that extraperitoneal section has a definite place in the hands of surgeons properly trained in this procedure. It is a reasonably complicated operation, however, and the peritoneum can easily be torn, thereby potentially infecting the peritoneal cavity. Hysterectomy following cesarean section in infected cases still has a valuable place in obstetrics. In this procedure the focus of infection is removed, and even though future child bearing is eliminated, a more rapid recovery with less residual pelvic disease can be expected

TOXEMIA

An excellent review of the toxemias of pregnancy has been published by Kellogg,¹⁹ who states the present situation of this disease with great clarity. "Little advance has been made in our understanding of the problem of hypertensive albuminuric pregnancy." He emphasizes the fact that the residual lesion after pre-eclampsia is invariably hypertension, with an incidence of 50.9 per cent, the incidence after eclampsia is increased to 60.8 per cent. Kellogg has never found glomerular nephritis in any patient as the result of eclampsia. The older the patient, the greater her pancy, the higher the blood pressure

during pregnancy, and the longer the duration of the illness, the greater the liability of the ultimate occurrence of hypertension. These factors are of extreme importance in the decision regarding treatment and the desirability of future pregnancies. It should always be remembered that the patient may have to pay in later years for an unduly prolonged pregnancy and that each succeeding pregnancy may add to this price

Kellogg recommends Veratrone as offering the fastest method of controlling convulsions in eclampsia. It also lowers the blood pressure in patients with pre-eclampsia who are on the verge of convulsions and thus greatly increases the safety of emptying the uterus. He states that this drug should be used in conjunction with magnesium sulfate. Veratrone will not save patients with severe eclampsia

The work of Smith and Smith²⁰ has shown that there are high levels of chorionic gonadotropin and low estrogen activity in the blood and urine of toxemic patients. There is also a deficiency of progesterone. This same situation occurs normally just before and during labor, and is in progress weeks before the development of toxemia. Fortnightly quantitation of serum gonadotropic hormone after the fifth month will demonstrate an abnormal rise in the level of this hormone eight to two weeks before the disease becomes clinically apparent in about 80 per cent of cases. The clinical application of this work has been most successful in pregnancy complicated by diabetes, in which the patients are particularly prone to develop toxemia

Hertig²¹ has developed a comprehensive view of toxemia of pregnancy that implies that many of its manifestations result from the same fundamental cause. He states that eclampsia, toxic separation of the placenta, cortical and pituitary necrosis and placental degenerations are all closely allied. A classification of separation of normally implanted placenta based on disease fixes the blame for mortality of this condition—almost, if not wholly—on the toxic variety. In proof of this statement, Hertig gives statistics to show that cases of toxic premature separation of the placenta treated by hysterectomy, rupture of the membranes, with or without vaginal packing, Spanish windlass or Pitocin show approximately the same maternal mortality—15 per cent

Some placental degeneration occasionally occurs in all cases grouped under the American classification of "hypertension of pregnancy," including "minimal toxemia," and prompt action can avert fetal death from this placental damage. With this placental degeneration the fetus may cease to grow. The smaller the baby, the more certain the presence of placental degeneration and the more important to remove the fetus from the uterus. These babies act their gestational age and are much better risks than normal premature babies of the same weight.

Cosgrove and Chesley²² state that the most significant and universal pathologic tendency in toxemia is definite functional and structural change in the vascular system, particularly the capillaries and arterioles. They point out that there is no general agreement regarding the existence of one toxemia of pregnancy, or whether a number of different causes may operate in the pregnant woman to give rise to a more or less similar group of manifestations. The only improvement in the treatment of toxemias is the average medical awareness of the potentialities for diagnosis and therapy in the earlier stages. Medical treatment should first be tried in all cases of toxemia of pregnancy, in patients who do not respond, termination of pregnancy is indicated. Cesarean section is recommended in culminating cases, but never after eclampsia has developed. The figures in 1625 cases of toxemia give a remote permanent hypertension in 53 per cent.

The most promising development regarding essential hypertension in pregnancy is the result obtained by the lumbodorsal splanchnicectomy of Smithwick.²³ In selected cases of young women with marked essential hypertension, this operation permits the patient to carry a pregnancy to a successful termination without damage to the vascular system. Fourteen patients with severe hypertension, relieved by operation, were successfully carried through pregnancy by Smithwick and Newell.²³ Of these, delivery was induced before term in 2 because of a developing toxemia. 1 case had a nontoxic separation of the placenta. These cases were of the type that ordinarily ends in disaster.

In conclusion, toxemia of pregnancy remains a disease of unknown etiology. Such improvement as has taken place in the incidence and treatment of this disease is due to its earlier recognition and to proper prenatal care. No specific curative treatment has as yet been found. Patients who do not respond to medical treatment should be delivered at the earliest possible moment by the simplest and least traumatic method. All women who develop this disease stand about a 50 per cent chance of subsequently developing a permanent hypertension. A long toxemic pregnancy, with repeated succeeding pregnancies, increases the incidence and severity of permanent hypertension.

ANESTHESIA

The addition of Demerol to the standard obstetric anesthesia with barbiturates has been well discussed by Irving²⁴ from experience at the Boston Lying-in Hospital. He reports that the combination of barbiturates with scopolamine obtains amnesia in 84 per cent of cases, whereas the barbiturates and Demerol result in satisfactory amnesia in only 70 per cent. The barbiturates and scopolamine have lowered the incidence of stillbirth and neonatal death, but there is some danger to the mother,

chiefly because of the possible appearance of edema of the lungs and other pulmonary complications during labor or delivery. This danger is avoided by the use of Demerol, which is rarely a respiratory depressant. The great advantage of the use of Demerol with scopolamine, instead of the barbiturates, is decreased restlessness during labor. So far as the effect on the fetus is concerned, Demerol is a much milder depressant. With barbiturates and scopolamine, only 62 per cent of infants breathe immediately, whereas with Demerol and scopolamine 82 per cent breathe at once. If the patient has become restless from the use of barbiturates, a shift to Demerol will greatly quiet her.

Much has been written concerning the use of caudal anesthesia in obstetrics. Hanley and Malone²⁵ report from the Los Angeles County Hospital on a series of 152 patients with no complications. They state that caudal anesthesia shortens the first stage of labor and prolongs the second, owing to the lack of the mother's voluntary expulsive power. The analgesia was successful in 96 per cent of cases. The single block is recommended as the most effective. Continuous caudal anesthesia requires the constant presence of a trained anesthetist, and many patients complain of backache following this procedure.

Andros and Henderson,²⁶ at the University of Michigan Hospital obtained complete relief of pain in 250 cases with continuous caudal anesthesia, without impairment of consciousness. There was no abolishment of voluntary motion or interference with uterine contractions. The respiration of the infant was not depressed, labor was shortened, and the blood loss was diminished. The incidence of operative delivery was definitely increased.

Hingson²⁷ presents statistics on caudal anesthesia in 42,000 cases. There were 7 maternal deaths due to misuse of the caudal analgesic, and 3 were regarded as anesthetic deaths. He states that complete block of the eleventh and twelfth thoracic roots gives complete relief. Uterine contractions continue if the analgesia does not go above the tenth thoracic root. Hingson believes that this anesthesia causes relaxation of the cervix by paralyzing the parasympathetic nerves. He recommends its use in toxemia, since it causes a definite hypotension.

Caudal anesthesia has definite possibilities in obstetrics, but it will probably not obtain general use at present. The difficulty of the technic as well as the danger involved if clumsily given, requires that it be used only by a trained anesthetist. The presence of an anesthetist for several hours during labor is not possible in the majority of cases.

Hellman and associates²⁸ report on the use of Pentothal Sodium. They claim that it should not be used for normal delivery and is indicated only in low-forceps delivery. They warn that the drug passes freely through the placenta, delivery should

therefore take place as soon as possible after the anesthetic has been given

In my opinion, spinal anesthesia, in the hands of a trained anesthetist, remains the choice for routine cesarean section. It is not only the most satisfactory for the operator but also appears to be the least upsetting for the patient. With the exception of occasional headache, it causes few postoperative complications.

THIRD STAGE OF LABOR

Aaberg and Reid²⁹ report on manual removal of the placenta at the Boston Lying-in Hospital. This series consisted of 217 cases, the incidence in all deliveries being 0.5 per cent. The chief cause was retention rather than hemorrhage. In this group there were 24 cases of placenta accreta. Prolonged labor was also an important factor in placental retention. The morbidity in this series was 28.8 per cent. The uterus was ruptured in 1 case. Four patients died following manual removal of the placenta, — 2 from infection and 2 from hemorrhage, — a mortality of 1.8 per cent. In 18 cases uterine tamponade was used, and the morbidity in these cases was 55.5 per cent.

This report emphasized, once again, the seriousness of manual removal of the placenta, which is a major obstetric procedure. Proper management of the third stage of labor is extremely significant. Attempts to express the placenta before it is fully separated are a frequent cause of excessive blood loss. Rough and careless handling of the uterus often starts hemorrhage. Excessive hemorrhage is the only indication for immediate removal of a retained placenta. Otherwise, it is better in the average case to wait at least two hours for a placenta to separate, since early interference may cause needless trauma and hemorrhage. A careful estimation of blood loss and the general condition of the patient permits the postponement of operative interference and frequently avoids it. Following delivery, the intravenous administration of Ergotrate hastens the separation of the placenta. Manual expression of the placenta should be avoided, if possible, until all signs point to a complete separation. If manual removal is necessary, a careful examination for placenta accreta should be made. If an accreta is found, no attempt at removal should be made — a hysterectomy is the only safe procedure.

PREGNANCY TEST

An additional pregnancy test has been developed that may well become a standard procedure. As reported by Robbins, Parker and Doyle,³⁰ it involves the use of the South African frog (*Xenopus laevis*). The great advantage of this test is its speed. It is easy to interpret and avoids the use of complicated histologic technic. It can be performed in any laboratory once the breeding and the care of the frogs can be satisfactorily accomplished. The reproductive life of the frog is ten to twelve years, and

they can be used repeatedly. After a positive test a frog may be used again in thirty days, and after a negative test, in five days. The test consists in the injection of an extract of urine into a female frog. In a positive test, the frog produces eggs within twenty-four hours, frequently, this takes place within eight hours. If no eggs are produced within twenty-four hours, the test is negative.

In a series of 100 cases there were no false-positive tests. There were false-negative reactions in 4 cases, 2 of which were tubal pregnancies and 2, early miscarriages, in these cases there was a low titer of the hormone. A larger amount of urine is now used in the test, with the result that there have been no false-negative reactions.³¹ It appears that the rat test is about six times as sensitive as the frog test. Although this makes no difference in normal pregnancy, in early and doubtful cases more urine must be used than is necessary in the rat.

CASF 33031

PRESENTATION OF CASE

A forty-three-year-old maintenance worker entered the hospital because of paralysis of the arms and legs.

The patient claimed to have been perfectly well until a week before admission, when he had a sudden onset of severe, cramping abdominal pains, with ten or twelve watery bowel movements during the day. He felt nauseated and vomited twice. No blood was noted in the vomitus, stools or urine. All the symptoms cleared on the following day. The patient felt well until three days before admission, when in the morning he was briefly conscious of a numbness and prickling sensation in both calves. That evening, he again complained of a severe sensation of "pins and needles" in both calves, lasting for half an hour. On the following day he first noted definite weakness, which made it difficult for him to rise from bed in the morning, and by 2 00 p m he was no longer able to stand. He believed that weakness had begun in the arms and legs at the same time, involving the distal muscles before the proximal ones, so that motions of the elbow and shoulder, knee and hip were retained after he was no longer able to move the fingers and toes. Forty-eight hours before admission he awoke with complete paralysis of the extremities, except for minimal motions at the shoulders and hips. He was unable to sit up in bed. He also began to complain of a moderately severe ache low in the back and of a slight ache in the arms and legs, but there was never severe pain in the extremities. The urine was noted to have a peculiar reddish-brown color, which it had never had previously, by the day of admission the color of the urine was again normal. There had been no weakness of the muscles of the face, dysphagia, dysarthria, respiratory difficulty, visual symptoms, sphincter disturbance, chills or fever. No drugs had been taken.

The past history was irrelevant except for mumps, measles, pertussis and diphtheria in childhood. The system review was negative, except as stated in the present illness. The patient's mother had died of abdominal sepsis. The father, six brothers and a

sister were living and well. There was no family history of infectious, degenerative, neoplastic or psychiatric diseases. The patient worked in a plant making rubberized cloth. No mention was made that other workers had had similar attacks, he was not known to have been exposed to toxic substances.

Physical examination revealed a complete, flaccid quadriplegia, except for slight elevation adduction at the shoulders, more on the right than on the left, and slight flexion and extension of the hips, also more on the right. No motions could be carried out against gravity. All motions of the neck were present, but there was weakness of flexion, so that the head could not be raised against gravity. The respirations were somewhat shallow, with some use of the accessory muscles. The rate was regular at 16 per minute. There was some contraction of the abdominal muscles, but weakness was marked. The patient was unable to maintain a sitting posture. There was complete areflexia including absent plantar responses. The only sensory abnormality was a questionable, minimal glove hypalgesia to just above the elbow. Light touch was intact, as were position and vibratory sensations.

The temperature was 98.6°F, the pulse 80, and the blood pressure 120 systolic, 80 diastolic.

Examination of the blood showed a hemoglobin of 15 gm per 100 cc and a white-cell count of 6600, with 75 per cent neutrophils and 18 per cent lymphocytes. The specific gravity of the urine was 1.025, and the pH was 4.5. There was a + test for albumin, and in the sediment an occasional granular cast was seen, although there were no white or red cells. The stools were guaiac negative. The initial pressure of the spinal fluid was equivalent to 130 mm of water. The total protein was 67 mg per 100 cc, and there were no cells. The gold-sol curve was 0001123311. The serum protein, sugar (fasting), calcium, phosphorus and phosphatase levels were within normal limits, as were the prothrombin time, the cephalin-flocculation test and an agglutination test with dysentery bacilli. An electrocardiogram and an electroencephalogram were normal. Stool cultures were negative for pathogenic organisms. Hinton tests of the blood and spinal fluid were negative.

On the day after admission there was no apparent change in the patient's condition. The vital capacity was 0.6 liter, the chest expansion was 0.5 cm. On the third hospital day a slight flicker of voluntary motion of the right patella appeared. At 10 00 o'clock that night the patient suddenly had respiratory difficulty, inability to swallow, marked accumulation of pharyngeal secretion and a weak voice, with loss of the higher pitches. There was no gag reflex. The facial and extraocular movements remained normal. He was placed in a respirator, and the pharynx was suctioned frequently. The bulbar signs subsided on the fourth day, but considerable respiratory difficulty remained. Outside the respira-

tor breathing was shallow, at a rate of 30 per minute. The electromyogram showed a low-voltage, repetitive discharge in the left and right extensor carpi radialis. This was also found in the left gastrocnemius muscle. These discharges were interpreted as similar to those seen in the neuritides.

Between the fourth and fifteenth hospital days the average temperature gradually rose from normal to 103°F. On the eighth day the urine became dark. On the ninth day there was fairly severe tenderness in the left lower quadrant and midline of the abdomen, without spasm. Peristalsis was normal. Marked signs of wasting were evident by the eleventh hospital day. A Levine tube was passed, and feedings were started. Penicillin therapy was begun on the next day, 15,000 units being given every three hours. On the thirteenth and fourteenth hospital days, livid, cool areas were noted on the arms and legs. On the nineteenth day there was a twenty-minute period of cyanosis, which began when the breathing became faster than the respirator impulses. Oxygen afforded improvement for several hours, but the patient suddenly became cyanotic and died.

DIFFERENTIAL DIAGNOSIS

DR. AUGUSTUS S. ROSE: No comment is made in the record concerning the mental status. I should also like to know if the blood pressure rose rapidly before death. I assume that the "dark urine" noted on the eighth hospital day was similar to that previously described.

DR. CHARLES S. KUBIK: There is not much said in the record about the mental state. Apparently, the patient was sufficiently conscious on admission to refuse intravenous medication. There are no further data regarding the blood pressure.

DR. MADELAINE BROWN: The mental state was normal, even when the patient was in the respirator.

DR. ROSE: In summary, this patient, without previous illness, developed a rapidly progressive motor paralysis involving the distal portion of the extremities first, then the trunk and neck and finally the muscles supplied by the medulla. It is peculiar, and I believe important to note, that paralysis of swallowing and difficulty in speaking improved after two days, although the respiratory mechanism remained impaired. The laboratory data showed normal routine blood findings and an essentially normal urine, except for the statement in the history that it was dark or dark red on two occasions. The total protein in the spinal fluid was 67 mg per 100 cc.

The symptoms, signs and course point clearly to a disease of the peripheral nerves. But the progression and the variability of the signs raise the question of central as well as peripheral involvement — suggesting the diagnosis of Landry's ascending paralysis. Landry's paralysis is not a specific entity but a condition that affects the lower spinal cord and fairly rapidly ascends to the medulla.

In this era of vitamins we must include vitamin deficiency in the differential diagnosis of any type of peripheral neuritis. In this case, however, there was no history of dietary deficiency or debilitating illness. The rapid onset and progression of the symptoms, as well as the variability of the paralysis, which I have mentioned, make vitamin deficiency unlikely. There was no history of ingestion of drugs or of contact with heavy metals. The abdominal pain raises the question of lead poisoning, yet in acute lead poisoning a different clinical picture is expected. On the other hand, infectious polyneuritis, or the Guillain-Barré syndrome, cannot be excluded quite so easily. This disease often appears following an upper respiratory infection or gastrointestinal upset. It frequently gives the picture of ascending Landry's paralysis, and some observers believe that there is involvement of the spinal cord and brain, as well as of the peripheral nerves. The spinal-fluid protein is elevated, without an increase in the cell count. Furthermore, in infectious polyneuritis it is not unusual to find motor paralysis with little or no sensory involvement. The diagnosis of infectious polyneuritis, however, does not give an explanation of the two striking and unusual features of this case: the abdominal pain and the two episodes of dark urine. These symptoms bring to mind the condition known as acute porphyria.

Acute porphyria is a condition that is probably congenital but may be acquired. It is of unknown etiology and is associated with episodes of dark or Burgundy-red urine due to an excess of porphyrin pigments and is often complicated by neurologic symptoms and abdominal pain. Last year Dr. Denny-Brown¹ published an excellent dissertation on the subject. He reported 2 cases, in 1 of which the patient recovered, the other patient died, and careful pathological studies showed spotty demyelination in the peripheral nerves and central white matter. Similar observations had been made by others. Dr. Denny-Brown, however, with his experience and observation on the effects of ischemia on the peripheral nerves, raised an interesting hypothesis concerning the pathogenesis of the neurologic signs in this disorder. Porphyrins apparently cause constriction or spasm of smooth muscle, as indicated by reported cases in which spasm of the colon was observed at operation and by others with constriction of the retinal arteries. Dr. Denny-Brown states that the pathological findings could be associated with ischemia due to intense arteriolar spasm. This is an engaging theory of the mechanism of symptoms but, of course, gives no clue to the etiology. Another article on the subject that should be mentioned is the monograph by Mason and others.²

Many of the patients in the reported cases of acute porphyria who died had had, prior to death, a severe delirium, coma and convulsions. Indeed, some patients who recovered had had such symptoms.

ce the disease occasionally occurs in several members of a family, we have a probable explanation for the inclusion of a negative psychiatric history in the record. Although the patient with acute porphyria may die in the first attack, many recover, and the recovery is usually complete.

I can make no other diagnosis in this case than acute porphyria with neurologic complications. It will be of interest to know whether tests for the detection of porphyrin pigments were done.

DR BROWN: Tests were performed and were positive. The interesting thing about this patient to me is that the spinal-fluid protein was increased.

DR ROSE: Yes, I should have mentioned that. In the cases reported in the literature the total protein of the spinal fluid was usually normal. I have no explanation why it was elevated in this case.

DR BROWN: Acute porphyria is the diagnosis that was made clinically.

DR ISAAC TAYLOR: Dr Kubik has asked me to say a few words about the condition known as acute idiopathic porphyria. The clinical features have been described by Dr Rose. When this patient came into the hospital the service believed, as Dr Rose did, that because of the neurologic findings, the dark urine and the abdominal pain, he was probably suffering from acute idiopathic porphyria, and the diagnosis was supported by the demonstration of a positive test for porphobilinogen in the urine. I might describe this test briefly. It has been observed that urine from patients suffering from acute idiopathic porphyria give strongly positive tests for urobilinogen with Ehrlich's reagent. The compound giving the red color with the aldehyde reagent is different, however, from urobilinogen in that it is insoluble in chloroform, whereas the red color produced by urobilinogen is easily soluble. Schwartz and Watson³ have studied these phenomena and have evolved therefrom a simple test that, when positive, is considered specific for acute porphyria. Ehrlich's reagent is added to urine from a patient with a suspected case, and the mixture is buffered with sodium acetate. If a red color develops, chloroform is added, and the mixture is shaken vigorously. The red color due to urobilinogen will be extracted quantitatively into the chloroform layer, if any red color remains in the aqueous phase, it is due to porphobilinogen and the test is positive. This is said to be a specific test for acute porphyria and is recognized as a simple method for testing for this condition. One should think of the diagnosis of acute porphyria in diseases characterized by atypical abdominal complaints, particularly cramps, nausea and vomiting, for which no organic lesion can be demonstrated. Nervous-system manifestations need not be present. The combination of abdominal pain and peripheral neuritis strongly indicates the diagnosis. The urine is ordinarily red during the acute attacks but not necessarily so.

This test affords a convenient way to demonstrate abnormal porphyrin compounds in the urine.

The mortality in cases of acute porphyria with neurologic complications is given in the literature as 50 per cent. We have seen 2 cases in this hospital during the past year, in both of which the patient died. As previously mentioned, one of Dr Denny-Brown's 2 patients survived.

CLINICAL DIAGNOSIS

Acute porphyritic polyneuritis

DR ROSE'S DIAGNOSIS

Acute porphyria, with neurologic complications

ANATOMICAL DIAGNOSES

Porphyruric polyneuritis

Bronchopneumonia

PATHOLOGICAL DISCUSSION

DR KUBIK: There is little or no question regarding the diagnosis of porphyria, which is established by the history and biochemical findings. There was bronchopneumonia, which was probably the chief cause of death.

In the peripheral nerves there were marked degenerative changes affecting a large proportion of the nerve fibers. Among these myelin sheaths were swollen, constricted, incompletely divided into short segments and, in many instances, broken up into rounded fragments. There were many fusiform enlargements and constrictions of the axis cylinders. In the spinal cord there was an axonal reaction of the anterior-horn cells. This change, consisting of a swelling of the cell and central chromatolysis of the Nissl substance, is secondary to disease of the axons of the cells peripherally and does not indicate primary disease of the spinal cord. It is, as a rule, a reversible reaction and does not lead to destruction of the cell.

The nuclei of the seventh cranial nerve were not remarkable, and I was unable to find a section of the medulla through the ventral nuclei of the tenth cranial nerves. There was no degeneration of myelin, and aside from the axonal reaction, no other lesion in the cerebrum, cerebellum, brain stem or spinal cord. The changes observed were those of a peripheral polyneuritis, there was nothing in the peripheral nerves or elsewhere that would enable one to make a diagnosis of porphyria. I do not know how to account for the neuritis or for the abdominal symptoms that are often observed in these cases.

CASE 33032

PRESENTATION OF CASE

A fifty-nine-year-old civil engineer was admitted to the hospital because of back pain.

The patient stated that he had occasionally had a stiff back all his adult life, but that the first incapacitating pain had occurred ten years previously. Strapping afforded sufficient relief to allow him to resume work. Eight years before entry he began to have pain in the lateral aspect of the right thigh, without associated back pain. This was noted while he was driving his automobile. The pain continued, and several months later a severe pain in the flank suddenly developed, immobilizing the patient in bed for about three weeks; he also developed a decubital ulcer. A physician told him that he had a "slipped" lumbar vertebra. Following this episode he was fairly well until three years before entry, when he again had moderate pain in the lumbar region requiring two or three days of bed rest. He subsequently had three or four similar attacks. Two years before admission he began having vague pain in the right hip and buttock, largely on motion or jarring of the right leg. Consultation with several physicians gave little benefit, and there was occasional extension of pain to the lower abdomen, associated with diarrhea. A barium enema gave normal findings. The teeth had been removed about seventeen months previously, without benefit. Several months later the patient had another attack of severe back pain and pain down the right thigh, requiring complete bed rest. He was seen by an orthopedic surgeon, who took x-ray films and advised a fusion, which was refused. A brace was applied, and the patient then stopped working for a year and went to the country, spending much time in bed. Six months before entry, while in a wheel chair, he rolled backward off a low porch, jarring his back. The resultant pain was so severe that he remained in bed for two weeks. For several months before admission he had stiffness and an occasional pain in the left shoulder. During the last two weeks he had noted pain down the lateral aspect of both thighs. He stated that this had never extended into the feet and that he had had no paresthesias; there was questionable numbness of the left anterior thigh, however.

On physical examination the patient experienced considerable difficulty sitting up in bed and getting into a standing position. There was marked limitation of flexion of the spine. Extension was restricted to about 5°, and lateral bending to about 20° either way, but without much lumbar motion. Tapping anywhere from the region of the third lumbar to the first sacral vertebra caused diffuse pain in the right buttock, but no point tenderness or deformity was noted. Straight-leg raising was possible to 70° on the left and 75° on the right, both limited by tightness of the hamstring muscles. Reflexes of the

knee and ankle were normal except for a slight increase of the patellar reflex on the right. There were no sensory changes. There was some limitation of abduction of the left shoulder. Examination was otherwise negative.

The temperature was normal, and the blood pressure 118 systolic, 65 diastolic.

Laboratory examination, including the red-cell count, the hemoglobin, the differential count, a blood Hinton test and the urine, was normal. The white-cell count was 11,700. The urine was negative for Bence-Jones protein. The total serum protein was 6.5 gm per 100 cc, with an albumin-globulin ratio of 2.0.

X-ray examination revealed a compression fracture of the third lumbar vertebra (Fig 1), with an extensive overgrowth of bone about the vertebral margins. There was definite irregular rarefaction throughout the collapsed body, and the intervertebral disks were preserved. There was no evidence of a paravertebral mass. There was slight anterior displacement of the body of the fifth lumbar vertebra on the sacrum, as well as a defect in the pedicles of the fifth lumbar vertebra. The abdominal aorta was calcified. The bones of the pelvis showed slight generalized decalcification but were otherwise normal. X-ray films of the skull, dorsal spine, ribs, femurs, left shoulder and chest and intravenous pyelograms were normal.

An operation was performed on the twelfth hospital day.

DIFFERENTIAL DIAGNOSIS

DR CHARLES S. KUBIA: The diarrhea was probably unrelated, but occasionally with lesions of the lumbar spine the pain is referred to the lower abdomen, even though that is above the level of lumbar dermatomes.

"The teeth had been removed about seventeen months previously, without benefit." It was not necessary to add the last part of that statement.

Apparently, there was some subjective sensory disturbance on the left side, most of the pain was on the right.

There was considerable discrepancy between forward bending or flexion and straight-leg raising. Forward bending and straight-leg raising are usually restricted to approximately the same degree. It is possible, I suppose, that the symptoms in this case were aggravated in the upright position and relieved by lying down.

The chief and only important symptom was pain. This was of the type caused by intraspinal disease in the lumbar region. The pain in the lower back in these cases is presumably a local effect, whereas that in the left side is referred pain, owing to compression or other involvement of the lumbar or sacral nerves. In the present case it is quite possible that all the leg pain was due to involvement of one pair of spinal nerves. There was no obvious weak-

s, sensory impairment or disorder of sphincter control to indicate involvement of the whole cauda equina, although some degree of such generalized involvement may have been present. Even with a large tumor of the cauda equina the neurologic examination is sometimes negative. It is quite possible that in this case lumbar puncture below the lesion or double lumbar puncture above and below would have revealed a subarachnoid block and increased protein at the lower level. But if there was no compression it was not severe enough to cause

of the body of the third lumbar vertebra, with the same bone destruction throughout the body and a considerable amount of overgrowth of new bone about the margin. The x-ray appearance is definitely that of a pathologic fracture, but the new bone formation is rather unusual for a malignant tumor.

DR KUBIK: That is not exactly what I expected to see. Would you say that these are congenital defects at the fifth lumbar vertebra?

DR LINGLEY: I think that there was some dispute about that. But usually such a lesion is con-

FIGURE 1

any obvious impairment of function. X-ray examination revealed a compression fracture of the third lumbar vertebra, since the character and distribution of the pain described fit a lesion at that level and in the absence of any better alternative lead, I assume that the fracture was responsible for the symptoms.

May we see the x-ray films?

DR JAMES R. LINGLEY: These films, taken at another hospital about ten months before admission here, show the slight anterior displacement of the body of the fifth lumbar vertebra, as well as some compression of the lateral border of the third lumbar vertebra with a break of the cortex at that point. In the lateral view there is bone destruction throughout the vertebral body. These films taken in this hospital, show a well marked compression fracture

considered to be congenital. It may be traumatic but is likelier to be congenital.

DR KUBIK: When I went over the clinical summary I supposed that the defects and anterior displacement of the fifth lumbar vertebra were probably due to spondylolisthesis, that condition might explain the early attacks of stiffness of the back, which were probably not related to the attacks of severe low-back and leg pain that began ten years before the patient entered the hospital. Those could be explained by the fracture of the third lumbar vertebra so that one must think of a condition that had existed over a long period and finally resulted in a pathologic compression fracture. I had in mind a hemangioma which is a frequent tumor of the vertebrae and often asymptomatic but which occasionally results in symptoms without fracture. I

thought that the hypertrophic changes were the result of superimposed trauma and did not indicate an osteoblastic type of tumor

A comparison of the two sets of films shows that a marked change had taken place in a comparatively short time. It seems to me that there is too much destruction for hemangioma. I suppose that I shall have to revise my opinion to include a more malignant type of tumor, but the character of the symptoms had been essentially the same for a period of ten years, that fact certainly indicates that they were being caused by the same condition all that time. Other tumors that might occur in this locality

chondroma, osteochondroma, chordoma, giant-tumor and perhaps osteoid osteoma. Chordoma may be a slowly growing tumor and may, I suppose, be a possibility. Myeloma, which may occasionally be a solitary lesion, is another possibility. I recall a case in which the diagnosis was made by Dr. Holmes from the x-ray findings and in which symptoms had existed for eight years, some x-ray treatment has been given and may have prolonged its course. The case under discussion today was a tumor of some kind, but I am not able to say exactly what.

DR. TRACY B. MALLORY: Have you an opinion, Dr. Sosman?

DR. MERRILL C. SOSMAN: It looks like a central tumor in the vertebra. I believe that the important approach is to determine the point of origin, whether primarily in the spinal canal, with secondary erosion of the bone, or primarily in the bone and secondarily involving the canal. I think that the latter is more probable from the x-ray appearance. The most frequent of these is the giant-cell tumor, which of course may last for many years, or a solitary myeloma. The original films show erosion of the pedicle on the right side. This pedicle is missing on the right side of the third lumbar vertebra, and the

adjacent lamina and articular processes are destroyed, so that it is invading the surrounding portion of the spinal canal at that point. Giant cell tumor may do that, as well as solitary myeloma.

DR. JOSEPH S. BARR: I think that we ought to add tuberculosis to the list of diagnostic possibilities. Central tuberculosis of bone in adults may remain in a semiquiescent stage, with mild symptoms for a long period, producing hypertrophic changes, not only in the spine but also in the knee. I do not know that that is the diagnosis, but I should like to raise the possibility.

DR. GRANTLEY W. TAYLOR: No one mentioned metastatic carcinoma, which is by all odds the most frequent cause of such a destructive lesion in bone.

DR. LINGLEY: I interpreted these films and put myeloma first, chordoma second and hemangioma third.

CLINICAL DIAGNOSIS

Tumor of third lumbar vertebra

DR. KUBIK'S DIAGNOSIS

Tumor of third lumbar vertebra

ANATOMICAL DIAGNOSIS

Chordoma of third lumbar vertebra

PATHOLOGICAL DISCUSSION

DR. MALLORY: The operation on this patient was exploratory for the purpose of biopsy to establish a diagnosis. A destructive lesion of the vertebra was found, and the biopsy showed the characteristic histologic picture of chordoma. These are often slowly growing tumors for a long time, but then they may suddenly pick up more rapidity of growth and extend widely in a comparatively short period.

WHAT IS EPIDEMIC DIARRHEA OF THE NEWBORN?

RECENTLY the Committee on Problems of the Newborn Infant of the District of Columbia Section of the American Academy of Pediatrics¹ described epidemic diarrhea in the following manner

An infant in the neonatal period who previously well, suddenly passes one or more very loose or liquid stools combined with sudden abnormal loss of weight (after the period of initial weight loss) or one of the other symptoms associated with this type of diarrhea, such as vomiting, listlessness, drowsiness, refusal of feeding, short feeble cry, pallor or elevation of temperature, should be immediately isolated and reported to the hospital authorities as a suspected case of infectious diarrhea

The committee further recommended that should similar symptoms develop in another exposed in-

fant, both the suspected case and the new case should be reported to the health department as cases of infectious (epidemic) diarrhea. The decision whether the suspected case should be reported was the responsibility of the health department

Although recognition of this syndrome during the course of an epidemic is a fairly simple matter, the diagnosis of the first or even the second case often presents considerable difficulty. Infants are peculiarly subject to diarrhea, which may be caused by a large variety of conditions. The lack of knowledge regarding the etiology of epidemic diarrhea of the newborn adds to the confusion that obscures diagnosis in the individual case. For this reason most health departments have hesitated to include epidemic diarrhea of the newborn among the reportable diseases. In Massachusetts the problem is still further complicated because of a law that requires local jurisdictions, under certain circumstances, to assume financial responsibility for the care of persons ill with diseases declared reportable by the Department of Public Health.

If epidemic diarrhea of the newborn were declared a reportable disease, a thorough inspection of each nursery in which a case or a suspected case had appeared would have to be made by the proper health authority, otherwise it would be pointless to report the disease. Because of the large number of cases of diarrhea that occur among newborn infants, this would throw a sizable burden on health agencies. Furthermore, investigations would have to be instituted in many cases in which the diagnosis would prove to be incorrect. Perhaps a more logical control program would consist of periodic inspections of all hospital nurseries to ensure that institutions providing care for the newborn were operating according to standard procedures. Since in Massachusetts the Department of Public Health has been empowered to license hospitals, including those with maternity wards, this agency has the authority to make such inspections.

Investigation of several outbreaks of epidemic diarrhea of the newborn, as reported elsewhere in this issue of the *Journal*, has revealed many inadequacies in the care of the newborn in those hospitals where outbreaks occurred. In several hospitals overcrowding in the nursery, insufficient personnel, im-

proper making of formulas and faulty sterilizing technics emphasize the need for greater diligence on the part of those responsible for the care of newborn infants. Laboratory examination of so-called "sterilizing solutions," nipples and other utensils used in the nursery frequently showed heavy bacterial contamination. The presence of Group D streptococci in the noses and throats of infants ill with epidemic diarrhea suggests that these babies had been exposed to organisms normally found in the human intestinal tract. *Salmonella* infection of the newborn, three outbreaks of which have been reported in Massachusetts,² is further evidence that because of poor technics in the nursery infants are exposed to intestinal pathogens. In a recent investigation of *Salmonella* infection on a pediatric ward, it was found that individual thermometers were not available for each patient.³ Cultures of these thermometers after they had been "sterilized" revealed bacterial contamination. Similarly the vaseline used as a lubricant on the thermometers was also contaminated. Such faulty procedures provide ready means of transmitting infection from infant to infant.

Although infant mortality rates have declined considerably, neonatal death rates have remained fairly stationary. In a state like Massachusetts where the great majority of births occur in hospitals, it is obvious that the problem of neonatal mortality is intimately associated with events in such institutions. A recent report by Frant and Abramson⁴ indicates that the persistently high incidence of mortality among the newborn in New York City is due, in a great measure, to diarrheal disease. They found a steady rise from 1926 to 1936 in deaths due to diarrheal disease during the neonatal period.

It is apparent that, because of the large number of births that take place in hospitals, the matter of adequate infant care must be the direct concern of each administrator. Proper supervision of nursery technics and formula-making methods should be routine practice in all hospitals. Periodic inspections by health departments, including conferences with nursery supervisors on infant care, would constitute a real contribution toward the solution of this problem. Such a program would be a more practical and useful preventive measure than the routine

reporting of all cases of suspected epidemic diarrhea to the local health department.

URBAN STAKE IN RURAL HEALTH

THE status of health and medical services in rural communities is not in itself a responsibility of physicians living and practicing in cities, although members of the medical profession in all areas regret the fact that adequate medical care appears to be beyond the reach of a large segment of the population and wholeheartedly approve of conscientious and workable plans to remedy the situation. The matter concerns urban physicians, however, when proposed legislation to improve medical facilities in rural areas is intimately related to the practice of medicine throughout the United States, it is the duty, as well as the privilege, of the medical profession to give the closest attention to all such proposals. An example of this type of legislation is afforded by certain provisions of the Wagner-Murray-Dingell Bill, which are designed to make the Bill palatable to organized farm groups.

This is not to deny that improvements in rural public health and medical practice are needed or to minimize the efforts of physicians all over the country to investigate the problem and recommend a solution. At the first annual meeting of the National Conference on Rural Health, the inadequacy of public-health departments in rural areas, the high maternal and infant mortality in those areas as compared with the cities and the lack of well trained physicians in the small towns received close attention.¹ The medical profession was urged to sponsor and participate in plans to extend the benefits of prepayment medical care to people in the country. It was recognized that the problem involved is both economic and social, as well as professional, and the need for the establishment of health centers and for public-health education in rural communities was emphasized. It was also recommended that the kind of experiments envisioned in the proposed national

health legislation be limited to circumscribed areas the unfavorable experience with compulsory health insurance in Rhode Island being cited. The conference represents the determination of organized medicine to take active leadership in the movement to improve rural health and medical practice.

An encouraging aspect of the recent hearings on the Wagner-Murray-Dingell Bill was the farmer's opposition, as expressed by a spokesman for the National Grange, to the suggested extension of federal authority without the opportunity for the general public to express its opinion.² Of further interest is the fact that the Grange suggested means for remedying the deficiencies of rural health that are compatible with those favored by organized medicine. For once, the appeal to a special and powerful group contained in a bill that is a catchall for every scheme to improve medical care at the expense of individual freedom and initiative appears to have missed its mark. But the activity of the medical profession is still vital. In the words of Dr F S Crockett, chairman of the Committee on Rural Medical Service of the American Medical Association, "It is our duty to exercise the greatest vigilance wherever we believe our common interests are threatened through federal domination. There can be too high a price paid for help."¹

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

CHEEVER — Clarence A. Cheever, M.D., of Boston, died December 31. He was in his eighty-ninth year. Dr. Cheever received his degree from Harvard Medical School in 1885. Until his retirement in 1921, he practiced in Milton. A collection of historic microscopes was organized at Harvard Medical School largely through his efforts. A son, Dr. Austin W. Cheever of Boston, survives.

KERRIGAN — Joseph H. Kerrigan, M.D., of Stoneham, died January 3. He was in his sixty-second year. Dr. Kerrigan received his degree from Tufts College Medical School in 1907. He was a former president of the Middlesex East District Medical Society and was a fellow of the American Medical Association. For twenty-five years, he was chairman of the Board of Health in Stoneham. His widow, two daughters and a son survive.

TOZIER — Charles H. Tozier, M.D., of Winchester, died January 1. He was in his seventy-second year. Dr. Tozier received his degree from Harvard Medical School in 1901. His widow and a sister survive.

A HUNDRED YEARS AGO

Dr S. Brown of Wilmington, Massachusetts, reports that some atmospheric peculiarity prevailed in the summer and autumn of the past year which had an uncommon influence on the biliary organs of persons in his vicinity. Sporadic instances of icterus have made their appearance more or less every year, but the jaundice as an epidemic, until the summer and autumn of last year, had never to his remembrance met his observation. In some instances the disorder was complicated with typhus fever, but in more, the organs merely concerned in the digestive process suffered the effects of disease and gave evidence of local derangement. The symptoms in different individuals were nearly similar. At the commencement of the disease, a chilliness took place, with soreness about the gastric region on pressure, accompanied with flatulence and febrile symptoms, the urinary discharges were scanty and resembled bloody water from first to last, the skin began to show a slight yellow tinge, which progressed to an orange color in a few days more, when it began to assume a more natural color, and at the end of two or three weeks, the patient would resume his customary occupation if his disease was not complicated by typhus. The disease prevailed on both sides of the Merrimac as far up as Manchester, and probably farther, and whether it was solely endemic to the region of the Merrimac is a question he would like to have answered. The disease had the appearance in several instances of being contagious, but a contagious jaundice would be an anomaly. To what this disease may be attributed, there are various conjectures, whether to a state of the atmosphere, a deficiency of water in wells, or to the stagnant waters of the reservoirs connected with the lakes at the head branches of the Merrimac, let off to supply the factories below, is a question. He has had some suspicions that the last might be productive of a peculiar miasma which would specifically induce a diseased state of the biliary organs, because the water from these reservoirs was green and slimy, indicating its stagnated condition. — The whole number of deaths in Boston during the past year by the published General Abstract, was 3389, or 804 more than the year previous, of which 1472 were children under five years of age, over sixty years, 254. The number of deaths from consumption is put down at 485. With a population of 120,000, the mortality of Boston during the last year would thus be 2.82 per cent. — Influenza is prevalent at Bangor, Maine. In Baltimore it is also severe, and has even extended as far as New Orleans. — Dr. Kimball, of Lowell, amputated the hand of a young man who had been severely injured by a picker, the other day, having previously administered the letheon. The patient declared that he had not experienced the slightest degree of pain by the operation. — The special attention of medi-

cal gentlemen in the country is called to the regulations of the Massachusetts General Hospital in the admission of patients. The institution is admirably conducted, and may without hazard of contradiction be called the first hospital in America — The Vermont Medical Society has appointed Drs Charles Hall, C W Horton, A G Dana and Dyer Storer as its delegates to the National Medical Convention in May next — Dr Alexander E Hosack, of New York, has twice permitted the experiment of administering the ethereal vapor by Morton's apparatus, as preliminary to surgical operation, during the last week. The first case was an amputation of the thigh, the other case was the removal of a scirrhus testis which had acquired a formidable size. Both these patients testify to the entire unconsciousness which resulted from the inhalation, while the effects lasted — The Secretary of this Commonwealth makes a report annually to the Legislature of all the births, marriages and deaths which have been returned to him from the city and town clerks, and such other officials as are authorized to make these returns. No one believes the document to be just what it should be in point of completeness. We can only express a hope that this matter will finally receive that attention which its importance merits, both from the people of Massachusetts at large, and those whose duty it is to collect the information and transmit it to our indefatigable Secretary of State — Not long since, a public meeting was held in Boston to devise ways and means for providing the poor people of the crowded metropolis with better and cheaper tenements than they now have. One curious fact is apparent, viz that some of the poor seem to prefer dark, unventilated houses to better places. We most heartily pray that something may be done at once to better their state — One of the neatest things of the day has been sent abroad by Messrs Ticknor and Co of this city, entitled, "Memoranda for Young Practitioners in Midwifery, by Edward Rigby, second American edition, enlarged and improved."* Lilliputian as it is in its dimension, there are sixty-two closely printed pages of excellent material, which give correct information in the fewest words. We opine that a series of such miniature treatises, embracing medicine and surgery, that might be carried without inconvenience in a fob, would not only sell readily, but also be very much prized. Some who are always too busy to study large tomes, thus armed with accurate homoeopathic doses of professional knowledge, would perhaps have in their pockets more than they ever had in their head — Extracted from the *Boston Medical and Surgical Journal*, January, 1847

R F

*The Harvard Medical School copy of this Lilliputian miniature is inscribed "D. D. Slade from Prof W. Channing, Jan 1st, 1847. Slade then a medical student subsequently became professor of applied zoology."

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

NEW MOBILE UNIT FOR THE BLOOD PROGRAM

The Massachusetts Blood Donor Program of the Division of Biologic Laboratories will begin to operate a second Mobile Unit some time in February. With only one unit, the collection of blood has had to be limited to approximately one hundred pints per day. Another unit will make it possible to handle two hundred pints daily. Both units will be available to operate five days each week. If full schedules can be maintained for these units, present estimates indicate that fifty thousand pints of blood can be collected, processed and distributed during 1947.

At the beginning of the program the quota for each community was established at one donation for each 150 persons in the community. This quota has not proved sufficient to meet the demand, especially for whole blood, therefore it will be necessary to increase the annual quota of cities and towns participating in the program. New quotas will be raised to approximately one donation for each 100 residents.

Before the Mobile Unit visits a community, a representative of the Department of Public Health outlines the program to members of the local Red Cross chapter and interested social and civic organizations. Physicians and hospital authorities are urged to attend such meetings and to take an active part in the program. They are also invited to see the Mobile Unit in operation at any nearby location, and are welcome to visit the new blood-processing laboratory at the Division of Biologic Laboratories in Forest Hills. Staff physicians at the laboratory will be glad to discuss technics, the clinical application of blood products, the integration of state and community blood-procurement facilities or any other phase of the program.

MOBILE UNIT SCHEDULE

The Mobile Unit of the Massachusetts Blood Donor Program will make the following visits in the near future

PLACE	DATE
New Bedford	January 27, 28, 29
Stoneham	January 31
Quincy	February 3, 4
Concord	February 5
Cambridge	February 13, 14

BOOK REVIEWS

Dietotherapy: Clinical application of modern nutrition. Edited by Michael G. Wohl, M.D. With a foreword by Russell M. Wilder, M.D., Ph.D. 8°, cloth, 1029 pp., with 93 illustrations. Philadelphia: W. B. Saunders Company, 1945. \$10.00.

Here is a textbook almost certain to achieve popularity. It concerns nutrition, now a large cinder in the public eye. It is written by many authors, each an authority in the

particular compartment of nutrition that is his bailiwick. Each chapter is put together in a precise fashion, and a useful bibliography is appended. On the whole, therefore, any reader can easily plough through the whole field of nutrition and can dig deeply where he chooses. He can learn of everything from the normal diet to what is known of calcium and phosphorus metabolism, he can approach the vitamins in alphabetic sequence, or he can acquire up-to-date information regarding diet therapy whether it be for diabetes or in surgery, to make thin people fat or fat people thin, or influence the allergies or anything else.

The typography and illustrations are excellent. Best of all is the editing. For, despite the multiplicity of authors and subjects, the editor has succeeded in making each chapter read as if it had been written by himself, and hence as a whole the volume flows smoothly as though from a single pen. The book is highly recommended to students and practitioners for reference or steady use or even for the pleasure of reading a lively medical book on a topic that is currently of great general interest.

Rypins' Medical Licensure Examinations. Topical summaries, questions and answers. By Walter L. Biering, M.D., M.R.C.P. (Edin., hon.) With the collaboration of a review panel. Fifth enlarged edition. 8°, cloth, 546 pp. Philadelphia: J. B. Lippincott Company, 1945. \$6.00.

Dr Rypins published the first edition of his standard work on examination questions in 1933 under the title *Medical State Board Examination Questions*. Successive revisions were issued in 1935, 1937 and 1939.

The author was secretary of the New York State Board of Medical Examiners for fifteen years, and his original book and its revisions, constituting four editions, were based on a critical survey of thousands of questions actually used throughout the United States. Typical questions were selected and appended to the general review of the various subjects.

The work covers the whole field of medicine, including the basic disciplines, the specialties and general practice. Each section is preceded by a review of the subject under consideration. These reviews, which are well written and succinct, emphasize the important points of each subject. Technical procedures have been omitted.

After the death of Dr Rypins the editorship of a new, enlarged edition was intrusted to Dr Biering, who is well qualified to carry on the work, since he is secretary of the Federation of State Medical Boards of the United States and a member of the National Board of Medical Examiners.

The fifth edition carries out the original plan of separate summaries for each subject, with a selection of typical questions. The review sections were prepared by authorities in their fields. A new section on pharmacology has been added in recognition of the growing significance of this subject. Naturally, it is assumed that the candidates are adequately trained in the medical sciences, and therefore no attempt is made to teach them anything new.

A careful study of medical examinations in the United States indicated a general agreement among examiners regarding the material essential for candidates, and the present volume adheres closely to this groundwork.

The preliminary chapter, entitled "The Philosophy of Examinations" is an interesting review of the history of examinations in the United States and Great Britain.

The National Board of Medical Examiners is an important organization whose certificates are accepted by forty-five states and two territorial boards in lieu of the regular licensing examinations, as well as by the boards of England and Scotland for admission to the final practical examinations of these boards.

The text throughout is printed with a good, large type on soft paper, permitting extended concentrated study without visual fatigue.

This book is recommended as a reference source for all medical and public libraries.

Men under Stress. By Roy R. Grinker, M.D., and John P. Spiegel, M.D. 8°, cloth, 484 pp. Philadelphia: The Blakiston Company, 1945. \$5.00.

This book, coming up for review after the acute emotional emergencies of war have subsided, must be considered from two perspective planes. First, from the standpoint of the authors, the text material was composed in the heat of battle

to the accompaniment of pressures and directives from higher headquarters. The senior author, a neuropsychiatrist and psychoanalyst of no small professional stature, was subjected to conditions that threatened the ego of many if not all the psychiatrists in the service — not by life-or-death exigencies, but by constant subjugation to the inevitable regressively constituted elements of the military service. Adjustment to this set of circumstances resulted in the massive amount of productive energy that rolled this book and *War Neuroses* through the presses. The reviewer can personally recall similar vicissitudes so that the emotional tensions evoked by reading this book produce a sympathetic "me too."

From the standpoint of the content, the recounting of general psychiatric principles, even the rapid-fire disposition of the acute combat traumas that unleashed latent inflammable emotional reactions, the reviewer found ambivalent pleasure in reading and in identification. There are fairly comprehensive descriptions of the background and specific emotional stresses in aerial combat work, as well as of the various types of direct and late reactions noted in flying personnel. The use of Pentothal "narcosynthesis" (for effecting an abreaction of repressed traumatic material and then re-establishing ego-environmental integration via the imposition of the therapist as a kindly yet authoritative paternal symbol) was the chief therapeutic plan described. The reviewer regards this as another military emergency procedure substituted for more thoroughgoing psychotherapy.

The fluent, persuasive and authoritative style of the text may lead many readers to believe that when emotionally ill military personnel were released from the authors' care they were for the most part able to be returned to duty (only 2.3 per cent of the officers and 21.9 per cent of the enlisted men reportedly had to leave the service). The reviewer and many of his colleagues stationed at different convalescent or other hospitals in the Zone of Interior were frequently consulted about patients who had been under the authors' care at "The Don" and had been returned to duty — only to be separated from the service for formidable psychiatric disabilities. Not a few of these patients had been so imbued with the ritual of the "fiak juice" by contacts with other Don Cesar matriculants that they admitted to various entirely conscious expressions and outbursts delivered purely for the benefit of the therapists. This is not related in any derogatory manner, since similar occurrences punctuate any psychiatric practice, but for the record. Another item concerning flying personnel should be documented. A number of youngsters undertook flying training because the preliminary training period lasted in many cases for nine months or more before the trainee even sat in an airplane. Another several months elapsed before permanent assignment after wash-out. Consciously or unconsciously, a year or so before actual combat work took place, rather than the emulation of Icarus, was an important motivation in applying for this training.

The psychiatrically oriented reader at this date will find this book interesting and somewhat instructive. In the psychiatrist who was involved in the treatment of combat casualties considerable ambivalence may be provoked.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

The Extremities. By Daniel P. Quiring, Ph.D., head of the Anatomy Division, Cleveland Clinic Foundation, and associate professor of biology, Western Reserve University, Beatrice A. Boyle, artist, Cleveland Clinic Foundation, Erna L. Boroush, M.A., fellow, Anatomy Division, Cleveland Clinic Foundation, and Bernardine Lufkin, A.B. 8°, cloth, 117 pp., with 105 illustrations. Philadelphia: Lea and Febiger, 1945. \$2.75.

The purpose of the diagrams in this manual is to make clear to students the origin, insertion, action and arterial and nerve supply of the muscles of the upper and lower extremities, together with their motor points.

Modern Urology for Nurses By Sheila M Dwyer, R N, B S, director, School of Nursing and Nursing Service, Southampton Hospital, Southampton, New York, and George W Fish, M D, associate professor of urology, College of Physicians and Surgeons, Columbia University, New York City. With a foreword by Helen Young, R N. 12^o, cloth, 287 pp., with 66 illustrations. Philadelphia: Lea and Febiger, 1945. \$3.25.

This second edition of a standard manual for nurses has been revised throughout to provide for the advances in medical knowledge occurring since the publication of the first edition. The use of penicillin and the sulfonamides in the treatment of urinary infections has been included, and the sections on ureteral transplants have been greatly expanded, new material on the diagnosis of the treatment of cancer of the prostate has been added. In this edition an attempt has been made to place greater emphasis on the patient as an individual. The concluding chapter on a teaching program for urology has been completely rewritten, and the outline has been set up in question form.

The Yearbook of Psychoanalysis Volume I. Sandor Lorand, M D, managing editor. 4^o, cloth, 370 pp. New York: International Universities Press, 1945. \$10.00.

The first volume of this yearbook contains contributions from twenty authors dating back to 1942. This beginning date was chosen because it was considered advisable to republish some of the studies on war neuroses appearing prior to 1945. In the future, only current contributions will be published in the annual volumes. The papers are by eminent writers in the field of psychoanalysis and are mostly reprinted from other publications. They are brought together in one volume, however, for convenient reference. The first paper is a reprint of an English translation of Sigmund Freud's remarks on the theory and practice of dream interpretation, first published in 1923. This volume should be in all large medical libraries and in special libraries of neurology and psychiatry.

Prescribing Occupational Therapy By William R Dunton, Jr, M D. 8^o, cloth, 149 pp. Springfield, Illinois: Charles C Thomas, 1945. \$2.50.

This is a partial, revised edition of a book first published in 1928 and long out of print. A new chapter on rehabilitation has been added, and the references to the literature have been brought up to date. This brief text should be useful to all interested in the subject.

Annual Report of the Baruch Committee on Physical Medicine for the Fiscal Year April 1, 1944, to March 31, 1945. 8^o, paper, 82 pp. New York: Baruch Committee, 1945.

This first annual report of the Baruch Committee gives in detail reports from the teaching and research centers and the projects in physical medicine supported by grants from the committee. Twelve institutions were recipients of these grants. Seven million dollars was allotted for fellowships in physical medicine, and five fellowships were granted. The total disbursements for the fiscal year ending March 31, 1945, for research and fellowship grants amounted to \$1,111,250.

Our Inner Conflicts: A constructive theory of neurosis By Karen Horney, M D. 8^o, cloth, 250 pp. New York: W W Norton and Company, Incorporated. \$3.00.

In this monograph Dr Horney has offered new viewpoints on the neuroses. It is written not only for psychiatrists but also for those interested in applying psychoanalysis to education, social work and anthropology and for the layman opposed to psychoanalysis.

A History of Medicine By Douglas Guthrie, M D, F R C S (Edin.), F R S E. With an introduction by Samuel C Harvey, M D, William H Carmalt Professor of Surgery, Yale University School of Medicine. 8^o, cloth, 448 pp., with 72 plates. Philadelphia: J B Lippincott Company, \$6.00.

This is a short authoritative history of medicine, written in a pleasing style that is easy to read. Each chapter concludes with a list of books for further reading on the subjects discussed. Appended to the text is a classified bibliography of medical history.

Nursing and Nursing Education By Agnes Gehlman, R A, A M, professor of nursing and chairman of the Skidmore College Department of Nursing, New York Post-Graduate Medical School and Hospital. 8^o, cloth, 72 pp. New York: The Commonwealth Fund, 1946. \$1.00.

In this short monograph the author briefly discusses the development of nursing as a profession in the United States, beginning with the opening of schools of nursing in Boston, New York and New Haven in 1873 and of public health nursing in New York in 1877. Chapters on nursing supply and demand before and during World War II, personnel policies in the maintenance of standards, nursing education and the estimated nursing supply and demand in the post-war period follow. The monograph is issued under the auspices of the Committee of Medicine of the Changing Order of the New York Academy of Medicine. It is well written, and the material well organized. It should be considered a part of the study of medical care as a whole. It should prove of interest to all who are concerned with medical care and health, as well as those professionally engaged in nursing and nursing education.

Dr W C Röntgen By Otto Glasser, Cleveland Clinic Foundation. 8^o, cloth, 169 pp. Springfield, Illinois: Charles C Thomas, 1945. \$4.50.

This popular short biography of Röntgen is well written and covers the various periods of his life from his school years until his death in 1923. Naturally most of the text is devoted to the period, 1895 to 1897, when he made his remarkable discovery of the x-ray. Medical students should be encouraged to read this small book, which should be in the collections of all public and university libraries.

Profitable and Necessary Book of Observations By William Clowes. With introductions by De Witt T Starnes, professor of English, University of Texas, and Chauncey D Leake, M D, dean, School of Medicine, University of Texas. 8^o, cloth, 232 pp. New York: Scholars' Facsimiles and Reprints, 1945. \$6.00.

This reproduction of an early English imprint should be in all medical libraries. It includes Clowes's treatises on gunshot wounds and syphilis. There are also two short observations by G Baker on preserving dead bodies for a long time and on the nature and properties of quicksilver.

General and Plastic Surgery with Emphasis on War Injuries By J Eastman Sheehan, M D. 8^o, cloth, 345 pp., with 496 illustrations. New York and London: Paul B Hoeber, Incorporated, 1945. \$6.75.

This book presents operative technics for every part of the body, with emphasis on plastic surgery. The text, which is well printed on good paper and profusely illustrated, is followed by an adequate index.

NOTICES

NEW ENGLAND HEART ASSOCIATION

A meeting of the New England Heart Association will be held in the amphitheater of the Dowling Building, Boston City Hospital, on Monday, January 27, at 8 15 p m.

PROGRAM

Latent Rheumatic Myocarditis. Drs Joseph Rogers and Stanley Robbins.
Morphine Hypersensitivity in Kyphoscoliotic Heart Disease. Drs Kermit H Katz and Harold Chandler.
The Relationship of Pregnancy and Subacute Bacterial Endocarditis. Dr Burton E Hamilton.
The Value of a Special Precordial Lead and Carotid Sinus Pressure in the Electrocardiographic Diagnosis of Tachycardias. Drs Laurence B Ellis, Leslie Lannon and James M Faulkner.
Interatrial Block. A case report. Dr Richard A Bloomfield.
Interested physicians and medical students are invited to attend.

CARE OF THE PATIENT BEFORE AND AFTER OPERATION*

With Special Reference to Fluid Requirements and the Importance of the Weighing Scale in Evaluating the Status of Hydration

OWEN H. WANGENSTEEN, M.D.†

MINNEAPOLIS, MINNESOTA

THE subject assigned to me has to do with the safe conduct of the patient through his operation. And if all the answers to all problems bearing on such an issue were available to the surgeon undertaking an elective operation, his course of action would unquestionably be altered in many circumstances. The items that assure safe conduct of a patient through the hazards of an operation might well be discussed under the following three headings: the preparation of the surgeon, the preparation of the dissection and the preparation of the patient and his care after operation.

The adjudication of the element of risk alone is an item of great importance not only to the surgeon but also to the patient who assumes the risk.

PREPARATION OF THE SURGEON

A realistic approach to the appraisal of risk is obviously necessary and involves not only the item of whether the patient has been prepared adequately for the procedure but also the matter of whether the surgeon's preparation has been adequate. Surgical specialty boards affect to be able to determine what surgeons are proper persons to operate for the relief of certain surgical disorders. And already in consequence of the work they are doing, a noticeable improvement has become discernible in the quality of surgical practice — an impetus that will gain momentum with the years. Yet there are considerations of an intangible nature, relating to the surgeon's preparation, that have an important bearing on the outcome of an operation and are not readily susceptible of analysis. Has the surgeon scheduled more operations than he can conveniently do in the

time he has allotted himself? Will he be hurried by prior commitments or appointments that may deter him from carrying out the plan of procedure with the usual care? A recital of such considerations and similar problems familiar to every surgeon can be embarrassing, it is perhaps best that I pursue the inquiry no further. It is to be remembered that surgeons are not immune from the trials of other mortals.

The following words of Portia in the *Merchant of Venice* on such matters are well known:

If to do were easy as to know what were good to do, chapels had been churches and poor men's cottages princes' palaces. It is a good divine that follows his own instructions. I can easier teach twenty what were good to be done than be one of the twenty to follow mine own teaching.

The qualities of which the surgeon stands in need have been enumerated as "an eagle's eye, a lady's hand and a lion's heart." However far these gifts may go in developing a good surgeon, they are not enough for the difficult surgical tasks of today unless that surgeon is fortunate enough to possess a sturdy pair of legs. Co-ordination of hand and mind is a vital requisite of precise and well performed surgery. Intentness of purpose, complete absorption in the problem at hand and a devoted consecration to his task — these are qualities that help the surgeon to dispel the fatigue and weariness of long and strenuous operative ordeals. There are times, indeed, when the surgeon appears to stand in need of special postoperative treatment: there are operations that tax the surgeon's endurance as much as the patient's ability to withstand them. But as the *Bible* tells us, "The sleep of a labouring man is sweet" and after a night of repose and rest — among the greatest of life's blessings — the surgeon returns refreshed to his labors.

Convalescence without complication is ordinarily synonymous with a well executed operative pro-

*Presented at the annual meeting of the Massachusetts Medical Society, Section of Surgery, Boston, May 23, 1946.

A meeting of the New England Heart Association will be held in the amphitheater of the Dowling Building, Boston City Hospital, on Monday, January 27, at 8 15 p m

PROGRAM

Latent Rheumatic Myocarditis Drs Joseph Rogers and Stanley Robbins
Morphine Hypersensitivity in Kyphoscoliotic Heart Disease Drs Kermit H Katz and Harold Chandler
The Relationship of Pregnancy and Subacute Bacterial Endocarditis Dr Burton E Hamilton
The Value of a Special Precordial Lead and Carotid Sinus Pressure in the Electrocardiographic Diagnosis of Tachycardias Drs Laurence B Ellis, Leslie Lannon and James M Faulkner
Interatrial Block A case report Dr Richard A Bloomfield
Interested physicians and medical students are invited to attend

(Notices continued on page xvii)

Pulmonary lobectomy provides an example. This operation was being done for bronchiectasis twenty-five to thirty years ago with an appalling mortality. Today, the same operation is being done in experienced hands in many places with a mortality of 1 per cent or less. Churchill, of this city, was the first to indicate that this potentially formidable procedure could be done at a risk comparable to that for excision of the acutely obstructed but unperforated appendix. This is an accomplishment of no small order. Yet all the essential items involved in the successful performance of this operation were known when the pioneers in the field were making their initial skirmishes with the problem. Now, however, the true significance of the pertinent knowledge relating to the problem has become known to the right persons. It takes time for the meaning of minor differences not apparent on first acquaintance with a problem to be appreciated. In other words, experience has been a great factor in reducing the mortality of pulmonary lobectomy from 50 to 1 or 2 per cent.

There were good surgeons twenty-five years ago, but surgical organization in well appointed hospitals is more efficient today. Anesthesia is considerably better, as is the knowledge of care of patients before and after operation. Surgeons have learned that it takes time and patience to do an operation well, and elimination of hurry by the surgical team has played an important role in the reduction of mortality. Improved nursing care has also been a factor.

Similar progress has been made with many operative procedures. Primary resection of the colon gave way to the exteriorization operation because the surgeon of that day was not ready for primary resection. Today, with a keener appreciation of the elements that are essential for the success of the procedure, well trained surgeons perform primary resection for cancer of the colon with a mortality of 5 per cent or less.

Experience

No less a person than the late Dr Harvey Cushing put considerable emphasis on the item of experience. In the fall of 1928, I had occasion to spend a week on the stand in his operating room at the Peter Bent Brigham Hospital. Each day he operated for a brain tumor. I marveled at his dexterity and nicety of technic and the facility with which he decided where the tumor was and what area of brain tissue should be excised. On leaving his clinic, I took occasion to thank Doctor Cushing for permitting me to sit in the stand day after day and watch him operate. I asked what the criteria were by which he decided so readily the area and extent of the excision of brain tissue. I was only partially prepared for his answer "Experience." I then asked if that experience could be resolved in terms of a definition. Dr Cushing replied again, "Experience." I countered by saying that in a case of breast tumor,

such characters as size, hardness and attachment to the skin helped the surgeon to determine the nature of the lesion. I asked if there were any parallel so far as brain tumors were concerned? Dr Cushing became a bit impatient with my impertinence and said again, "Experience." In the fall of 1934, Dr Olin West, secretary of the American Medical Association, gave an address at the Wisconsin State Medical Association Meeting at Green Bay, Wisconsin, in which he stated that Dr Harvey Cushing had emphasized the great value of experience in clinical medicine and had written an article on the subject. Failing to find the article in the *Quarterly Cumulative Index Medicus*, I wrote to Doctor Cushing. He appeared to have remembered the occurrence of 1928 and treated me somewhat more indulgently than when I had accosted him after a long and arduous operation. Although he denied having written philosophically concerning the importance of experience, Dr Cushing said, "If I spoke of experience, I undoubtedly spoke of technic." The intervening years have confirmed in my mind the truth of his emphasis on the great value of experience.

PREPARATION OF THE PATIENT

The customary technic of preparation of a patient for operation twenty-five years ago consisted essentially in giving a cathartic before operation and in repairing anemia by the transfusion of blood. With the resolution of the mystery that surrounded the cause of death in experimental pyloric and high intestinal obstruction by Gamble and his associates^{1, 2} in 1925, light and understanding came into the problem of fluid requirements of patients. During the twenty years that have elapsed, surgeons and other medical specialists have gradually been aroused from their apathy regarding the fluid and electrolyte requirements of patients. Collier and his associates^{3, 4} at the University of Michigan, for a period of many years, have been emphasizing the importance of evaluating daily the fluid and electrolyte requirements of surgical patients when the administration is parenteral. It is not long since, in many hospitals, when the fluid given parenterally to any patient was 0.9 per cent saline solution, whether or not glucose was included in the infusion. The hazard of the practice is not difficult to foresee, especially in an older age group of patients, in whom oliguria occurs more readily than in young robust persons. For every 6 gm of sodium chloride retained, approximately a liter of water is retained. When patients receive 18 to 27 gm of sodium chloride (2 to 3 liters of saline solution) a day and when their daily requirements, even in the early postoperative phase when abnormal losses must be covered, lie somewhere between 4.5 and 9.0 gm a day (0.5 to 1 liter of 0.9 per cent saline solution), it is understandable that difficulties arise with the maintenance of fluid and electrolyte balance. In

cedure Critical self-analysis with reference to the surgeon's responsibility for the occurrence of complications is the only rational attitude for the surgeon to assume. A surgeon who is Pollyannish in his attitude to his own accountability for postoperative complications shuns the growth and improvement that result from self-criticism and self-censure. Moreover, there are additional complications, such as thrombophlebitis, embolism, coronary thrombosis and cerebral hemorrhage, for which the surgeon is not strictly accountable, in that they are essentially unavoidable. Unfortunately, no absolute criteria are available to indicate whether or no these complications will occur, although in assuming certain operative risks, the surgeon is fully aware that he is overstepping the borders of convention in his anxiety to bring hope and relief from suffering to his patient.

PREPARATION OF THE DISSECTION

In any operation, preparation of the surgeon is important and implies a satisfactory preparation of the dissection — probably the most vital of all considerations in the safe conduct of a patient through an operation. Although the question of what or whose operation was done is significant, more important still for the immediate success of the procedure is *how* the operation was done. Nice anatomic dissections taking advantage of the knowledge of tissue planes, the careful dissection of blood vessels with minimal loss of blood, the precise placement of sutures and the gentle handling of all tissues — these are the items that ensure the immediate success of an operative procedure and the recovery of the patient. If, on conclusion of the operation, the surgeon is convinced that the objective of the operation was met satisfactorily and that the procedure was in accord with good physiologic principles, the ultimate success of the operation affords real promise of attainment.

No amount of excellent preoperative and postoperative care can make up for an operation that was badly done.

Fortunately, the emphasis on speed is rapidly disappearing from surgery. In another generation the heedless, reckless surgeon who is constrained to emphasize the element of hurry above every other consideration will have disappeared from the scene. And surgery will be the better when, in the memory of active surgeons, such meaningless claptrap phrases as "get in quick and get out quicker" have been completely forgotten. Perhaps we should begin by deletion of the word "theater" as the place where operations are done, operations have ceased to be spectacles, and they are dramatic only so far as they succeed.

The year 1946 marks the centennial of the first public administration of an agent to make operations painless and the coming of the beautiful word "anesthesia" by the medical poet, Oliver Wendell

Holmes. Relief from pain during a surgical ordeal — what a gift to humanity! Improved techniques of anesthesia, as much as any other consideration, have made it possible to eliminate the element of hurry in operations. The co-ordinated effort of anesthetist and surgeon can make an operation simulate physiologic sleep. There is much yet to be desired in the waking and recovery periods to make them less of a nightmare to the patient. Will the time ever come when an operation will be described as an experience not unlike a pleasant dream? We must of necessity be realists, nevertheless, this is a goal toward which surgeons should turn their eyes.

The use of dry sponges and the weighing scale constitutes an expedient that affords the surgeon satisfactory orientation concerning the extent of the blood loss at any juncture of the operation. To supplant, in kind and in amount, the fluid lost during operation serves to spare the patient the ill effects of protracted lag intervals in therapy.

One factor that bears on the success of operations cannot be stressed too much: deliberate thought and wise planning beforehand. This factor has to do with lessons learned and sometimes painfully in the process of critical self-analysis by realistic surgeons — perhaps best described as practical wisdom, an item on which I shall have more to say presently.

The Synthesis of New Facts

How does it happen that the surgery of today in certain fields can accomplish things that, in the light of the achievement of twenty-five years ago, must be considered no less than miraculous? To be certain, we of today have some new facts at our disposal. And a new fact can change the whole complexion of a problem. New facts, however, are surprisingly few. How many books contain a single new fact? The great impetus to medicine and surgery that comes from a few isolated key facts is astonishing. A general improvement in the tone of practice may be observed: witness what boons to medicine the sulfonamides and penicillin have been.

When the present accomplishment in a given field is compared with that of twenty-five years ago, the gain from the synthesis of known facts is appreciated. This circumstance is encouraging and should serve as a stimulus to all to ferret out from the scientific catacombs of libraries facts that, if known to the person who should be in possession of them, save endless labor and frequently supply the information necessary to the solution of a problem. It does, however, take experience and orientation to profit by reading and study in the interphases of one activity with other specialties. And for many, such vagrant rumination turns out to be wool gathering. Hence, the value of discussion groups such as this. The important thing is for the unknown knowledge to come into the hands of the person who is striving to effect the synthesis.

fluctuations in weight exceeding 3 per cent of the cooperative normal value suggest the necessity for closer scrutiny of the situation

Apart from patients with pneumonia, peritonitis and distention, from whatever cause, in whom the problem of fluid and electrolyte balance is often difficult, the predicament sometimes presents itself unexpectedly in patients who, in spite of a slow convalescence, were believed to have been progressing satisfactorily. The difficulty may be one of overhydration or dehydration. Neglect of weighing such patients is usually responsible for the delay in recognition. Yet, sometimes, especially in patients with complications such as distention, the situation develops so insidiously that the threatening difficulty of gains or losses in weight is not appreciated in time to avert the results of such fluctuations

Dehydration and electrolyte loss A loss of 5 to 6 per cent of the body weight, in consequence of abnormal fluid losses, is usually accompanied by recognizable clinical signs of dehydration and hypochloremia. If an inadequate amount of sodium chloride is given and 10 per cent glucose is injected intravenously, a liberal urine output may follow, and dehydration ensues in a few days if this electrolyte loss is not made up. If the fluid loss, responsible for the decrease in body weight, was occasioned by vomiting or suction applied to an intubated duodenal tube, alkalosis will usually follow, owing to a larger loss of the chloride than the sodium ion. In cases in which losses of intestinal secretions from the lower reaches of the bowel, as in diarrhea, are accountable for the contraction in weight, acidosis may occur. In either event, if no renal damage has occurred, saline solution is ordinarily a satisfactory repair agent, as Gamble⁶⁻⁸ has indicated.

Coller and Maddock⁴ suggested that dehydration and electrolyte loss be treated with saline solution, 0.5 gm of sodium chloride per kilogram of body weight being given for a depression in the plasma chloride of 100 mg per 100 cc below the normal value of 560 mg. It has been our practice in this clinic to proceed somewhat more cautiously, not giving nearly so much sodium chloride as is suggested in the Coller-Maddock rule, awaiting manifest evidence of diuresis before attempting to bring the plasma chloride value up to normal. Coller and his associates⁵ recently emphasized the so-called "salt intolerance" of sick surgical patients and characterized that clinical rule as "highly inaccurate and dangerous."

Zintel, Rhoads and Ravdin⁹ have employed 2 per cent solutions of ammonium chloride intravenously in the correction of alkalosis, believing that restoration of glomerular filtration will be quickened thereby. In the correction of severe acidosis a sixth molar sodium lactate solution¹⁰ or a 5 per cent solution of sodium bicarbonate may be used to restore the normal buffer values in the blood.

Overhydration Increases in body weight of 3 to 6 per cent may be unaccompanied by symptoms except edema. In old patients, whose physical status is poor, pulmonary edema, pneumonia and heart failure may result from too generous administration of sodium chloride. Not infrequently, when oliguria occurs in such patients accompanying the retention of water, the plasma chloride may remain low. Efforts to elevate the plasma chloride to a normal value by the administration of added sodium chloride intensify the difficulty. The usual initial provoking cause of the abnormal water retention and gain in weight in these patients is administration of more sodium chloride than the patient requires. Moreover, sodium chloride retention appears to occur in pneumonia¹¹ and in peritonitic states accompanied by intestinal distention. And, owing to impaired glomerular filtration,¹² severe oliguria may be present despite the fact that the body weight is above normal. In such cases, when the weight is 4 to 6 per cent or more above the initial normal level, I have contented myself with the slow intravenous administration of 800 to 1000 cc of a 50 per cent glucose solution a day, giving enough glucose to meet the basal caloric needs. The recovery from pneumonia, pulmonary edema and heart failure in such patients following the correction of the overhydration is often remarkable. There are mortality and morbidity of treatment, as well as of the disease process. And it is important to attempt to know which is which. When diuresis commences in such oliguric edematous patients, following fluid and sodium chloride retention, lesser concentrations of glucose with larger amounts of water may be given. For patients who have become oliguric or anuric because of renal damage from sulfonamide administration or a transfusion reaction, the dialysis of retained urea through the peritoneum by perfusion appears to be promising.¹³

Many of the situations that Jones and Eaton¹⁴ described in their excellent paper on nutritional edema were undoubtedly due to the excessive administration of sodium chloride. And whereas this agency, together with hypoproteinemia, may be a likely theoretical causal factor in bringing about obstruction at the efferent outlet after gastrojejunal anastomoses, I consider this item far less significant than overinversion of tissue by the surgeon in the making of the anastomosis.¹⁵ Early dismissal of patients from the hospital after gastrointestinal anastomoses of every kind is contingent on the making of satisfactory anastomoses that do not obstruct. It is time that surgeons appreciate that they themselves, in making imperfect anastomoses with overinversion of tissue, invite obstruction at the new stoma.

The Weighing Scale

Its accuracy in evaluating hydration For more than six years, in our clinic, the weighing scale has

this connection, it is not out of place to point out too that Collier and his associates,⁵ in 1944 revised downward their estimates of sodium chloride needs in the ordinary surgical patient

The Patient in Good Physical Condition

A patient who enters the hospital for a gastric resection for ulcer or carcinoma who is unobstructed and whose hemoglobin is 12 gm or better and who has been eating well and has not lost weight needs no special preparation for operation. A careful preoperative diagnostic study, inside or outside the hospital, including evaluation of the patient as an operative risk, is obviously indicated. The same principle holds generally, in my experience, for all conditions that come within the purview of the general surgeon. There are those who insist on several days of preoperative hospitalization, during which succinylsulfathiazole is given to patients expected to undergo resection for cancer of the colon. My thought and practice is to make every effort to effect a satisfactory anastomosis, a single row of interrupted silk sutures sufficing for any anastomosis from the stomach to the rectum. My experience has been that no intestinal antiseptics are necessary in the presence of a satisfactory closed anastomosis. If the anastomosis is unsatisfactory, all the drugs in the pharmacopeia are probably inadequate to correct the situation.

The Poor-Risk Patient

It is in the poor-risk patient that the following four items demand careful consideration: water requirements, electrolyte needs, loss of blood and caloric and nitrogen requirements.

Water and electrolytes. It is convenient to consider together the problems hedging about the administration of fluid and electrolytes to patients before as well as after operation. So much has been written about the fluid and electrolyte needs of patients that it would be out of place for me to restate what others, who have devoted serious study to the matter, have said before. In a sense, it is unwise to consider separately the need of a patient for water and electrolytes; they go hand in hand. When vomiting is absent, the patient slakes his thirst by drinking enough fluid to keep him comfortable. When fluids are administered para-orally, the urine output and the specific gravity of the urine serve as fairly satisfactory guides in determining how much fluid to give. The objective of the surgeon is to keep the patient in fluid and electrolyte balance, sparing him the ill consequences of large contractions or increases in fluid volume. Each morning, when the surgeon and his house staff make ward rounds, the fluid and electrolyte requirements of all patients not hydrating themselves are determined. The weighing scale is a worth-while agency in detecting early departures from the normal status of hydration. The urine output for the pre-

ceding twenty-four hours (6 a.m. to 6 a.m.) is noted together with the specific-gravity determinations of the urine, made by the nurse on the ward on three or four separate specimens. A twenty-four hour output of 1000 to 1500 cc, with a specific gravity in the range of 1.015 to 1.020, is regarded as optimal. These considerations hold for the period before as well as after operation. A fluid intake of 2500 to 3000 cc ordinarily takes adequate care of the situation. There is rarely any need to give patients fluid in the form of saline solution on the day of operation. Glucose solutions (5 to 10 per cent) suffice. If an inlying duodenal tube is in place to which suction is being applied, allowance must be made for loss of fluid and electrolytes through such an agency. A good working rule is to estimate the loss of sodium chloride at 5 gm per liter of gastric aspiration. The hazard of continuing to give saline solution after an inlying duodenal tube has been removed is real. Immediately after operation, owing to the vasodilating effects of anesthesia on the skin capillaries, the loss of water through cutaneous vaporization may be large. The face sheet of the hospital record provides space for all the items to be listed by the nurse. A careful appraisal of these various factors by the surgeon and his house staff once a day ordinarily suffices to keep the situation in hand. In cases in which the urine output for the preceding twenty-four hours falls below 800 to 1000 cc and the patient's weight varies more than 2 per cent from the preoperative normal, one of the surgical house officers reviews the situation again later in the day to ascertain whether the fluids and electrolytes outlined for the day at morning rounds were satisfactory.

The weighing scale is an important agent in keeping the patient in fluid and electrolyte balance. All patients on my service undergoing major surgery are weighed frequently — on admission and each day before surgery to ascertain the normal weight. The objective of the surgeon after operation is to keep the patient within a fluctuation that does not exceed or fall below the preoperative normal weight by more than 1 or 2 per cent. Fluctuations in weight of more than 3 per cent from the preoperative normal value are few indeed. Yet, strangely enough, such incidents can happen, usually when weighing has been discontinued because believed unnecessary. Constant vigilance on the part of the surgeon and his staff is necessary to obviate this type of occurrence. Gains in weight as well as losses may be observed.

In the normal course of events, a patient will have an indwelling duodenal tube in place after gastric resection for approximately forty-eight hours and after a colic resection for about seventy-two hours. In the postoperative period, the plasma chloride may be determined once or not at all, the urine output and specific gravity and the weight of the patient sufficing to denote a satisfactory status.

portable scale. A few months ago, Mr. John A. Melan, of the Scientific Apparatus Shop in the University of Minnesota, built for me a portable, bedside scale that permits weighing of the patient (Fig. 1). An electrically driven motor ele-

FIGURE 1 Scale Employed for Weighing the Patient in Bed

ates the patient in a hammock above the level of the bed (Fig. 2). This type of scale promises to prove helpful in dealing with sick patients. Weighing scales, like other apparatus, may go out of order and periodic checks for accuracy are imperative.

EXCHANGES BETWEEN THE INTRACELLULAR AND EXTRACELLULAR FLUID COMPARTMENTS

Hastings and Eichelberger¹⁶ observed that liberal amounts of normal saline solution injected intravenously into dogs caused a 48-gm gain per kilogram of muscle, detectable an hour after completion of the injection. In these experiments the dogs received 170 cc of saline solution (125 mg of sodium chloride and 25 mg of bicarbonate of soda) per kilogram. When, in addition, the hydrogen ion concentration was altered by the production of alkalosis employing a solution containing 114 mg of sodium chloride and 40 mg of bicarbonate of soda, the gain in weight per kilogram of muscle was 126 gm., of which amount the authors calculated the gain as 85 gm in extracellular fluid and 41 gm in intracellular. In other words, gains or losses in fluid sustained by the body are partitioned quickly,

in all likelihood according to a certain pattern, throughout the fluid-containing compartments of the body.

In studying dehydration Wiley and Wiley¹⁷ indicated that slight dehydration not exceeding 1.5 per cent of the body weight is probably unaccompanied by any great disturbance of the electrolyte balance. Inasmuch as 70 per cent of the body water is contained within tissue cells, it is apparent that ultimate fluctuations in the status of hydration of patients are due to contraction or swelling within them. Unfortunately, no direct means are available with which to measure changes in the intracellular fluid compartment, except so far as these changes are reflected in the extracellular fluids.

BLOOD LOSS

The employment of dry sponges that are weighed during operation permits the surgeon opportunity to inform himself concerning the extent of blood loss throughout the procedure. Only large packs in contact with the bowel are kept moist to keep fibrin formation at a minimum. The gain in weight of the sponges, passed back to be counted by the circulating room nurse, is calculated as blood loss, even though such gains in operations in the peritoneal and thoracic cavities are due in part to absorption of fluid other than blood. This scheme of calculating blood loss during operation has been in use in our operating rooms for somewhat more than four years.¹⁸ The plan has proved helpful, and a comparison with the usual colorimetric method for determining the blood loss suggests that this simple gravimetric method is quite accurate.¹⁹

In replacing fluid losses, there is no better rule than to replace in kind and in amount. In operations in which the anticipated blood loss is expected to exceed 500 cc, blood is always available for transfusion. In every major operative procedure, a needle should be placed in an ankle vein at the beginning of the operation, to permit the administration of glucose solution and blood or plasma if need be during operation. For blood losses in excess of 500 cc, there is no satisfactory substitute for the blood loss other than blood.

MAINTENANCE OF CALORIC AND NITROGEN EQUILIBRIUM

Within recent years, surgeons have become increasingly aware of the great importance of ascertaining the nutritional status of their patients prior to operation. It is not enough to make certain that the hemoglobin value is satisfactory and that the patient is in fluid and electrolyte balance. Patients whose food intake has been poor and who have lost considerable weight and, in consequence, have become autocannibalistic are poor subjects for operation. The protein stores of such patients have been depleted, and fatty infiltration of the liver is a usual sequel. The tolerance of such patients for

been employed as a matter of routine in computing fluid balance. Our experience suggests that the weighing scale is superior to other procedures in ascertaining early departures from the normal status of hydration in postoperative patients. In the weighing of patients the method can be carried out to an accuracy of about 100 gm. In a patient weighing 70 kg this figure represents 0.14 per cent of the body weight, in a patient weighing 50 kg, a margin of 100 gm in the accuracy of the method amounts to 0.20 per cent of the total weight. Since only changes ascribable to likely differences in the weight of body water are involved in attempting to follow the status of hydration with the weighing scale, employing the factor of 70 per cent of body weight as water, the accuracy indexes for patients weighing respectively 70 and 50 kg are 0.20 and 0.29 per cent.

For observations of an experimental nature, it is preferable to have a scale that weighs to an accuracy of approximately 5 gm. For clinical purposes, however, the ordinary weighing scale suffices. Over the short interval during the postoperative period, when the weighing scale is being employed to gauge the status of hydration, the error introduced, by assuming that observed changes in body weight represent differences in body hydration, is probably small indeed. The basal caloric requirements of the patient after operation are almost met by the daily intravenous administration of 3000 to 3500 cc of 10 per cent glucose solution. And the urinary nitrogen loss under these circumstances is ordinarily not large, especially when small amounts of plasma are given intravenously each day in an attempt to cover the protein demands of the body.

If the surgeon is relying principally on changes in the hemoglobin to afford the same orientation, it is obvious that this method is by no means so delicate as the weighing scales. A change of 1 gm in the hemoglobin from a previous determination of 13.5 gm suggests a 7.5 per cent alteration in hydration—a figure that is synonymous with severe dehydration or overhydration. Fluctuations of hemoglobin determinations in the normal patient in the range of 5 to 10 per cent are frequent enough in the experience of clinicians to suggest that adjudication of the status of hydration by changes in hemoglobin is not reliable, especially in detecting early or lesser variations in hydration. And it is just such early departures from the normal that the surgeon should be apprised of in following the status of hydration of his patient in an intelligent manner. It is fair to suggest that the weighing scale is probably twenty-five to fifty times more sensitive than the hemoglobin determination in the detection of minor changes in body hydration in postoperative patients.

In addition to the circumstance of greater accuracy over other available methods in determining the status of hydration, the weighing scale has the advantage of simplicity. Its chief virtue lies, however, in affording a prevision of what will happen

if abnormal losses or increases in body weight are not avoided.

Why have clinicians not adopted this device earlier to aid them in ascertaining the status of hydration of their patients? When will the weighing of cardiac patients become standard practice as a guide to therapy? In how many patients with urinary obstruction is the uremia observed after transurethral resection in reality extrarenal, owing to disorientation on the part of the surgeon in attempting to regulate fluid and electrolyte balance? Such patients as a group, because of their age and debility, are probably especially susceptible to errors in fluid therapy. Certainly, postoperative uremia is frequently observed among patients who were not uremic prior to operation. Is this circumstance inherent in the disease process, or is it a complication of therapy?

It is a frequent weakness to ask others to do what we might do better for ourselves. To this frailty, surgeons are no exception. We could weigh our patients, gaining thereby first-hand information relative to the status of hydration. But the laboratory will do this for us. We could examine the patient ourselves, but a note in the consultation basket to the medical staff will accomplish that objective more readily. We could make our own diagnoses, but why bother when we have roentgenologists and pathologists to make them for us? Have surgeons improved their technic by this sluggish indifference to some of their own important problems? When will they awaken from their torpid lethargy to a realization that they alone can significantly influence their own development? Other medical specialists are too occupied with their own problems to take a vital interest in ours. It is time that we grasp the necessity of helping ourselves out of some of our own difficulties. General recognition of the value of weighing patients will help the surgeon in his wrestle with the problem of hydration. Moreover, it is probably the best instructional agency in making a staff of both surgeons and nurses conscious of hydration. Of course, in many cases this extra labor is unnecessary. But who knows when this information will be at a premium? And who counts the cost of labor when lives are at stake? The time will certainly come when weighing patients will be as much a part of hospital procedure as taking the patient's temperature. Only time and patience, however, can overcome so powerful a force as the apathy of inertia.

Technic With the adoption of early ambulation of postoperative surgical patients as a frequent practice, most patients, on the day following operation, — even after major abdominal procedures, — are asked to stand on an ordinary portable scale brought to the bedside. Until recently, when patients returned from the operating room, they were lifted onto a Red Cross litter carrier, placed on an elevated block or platform on the same type of

table scale. A few months ago, Mr John A. Melan, of the Scientific Apparatus Shop in the University of Minnesota, built for me a portable, bedside scale that permits weighing of the patient in bed (Fig 1). An electrically driven motor ele-

FIGURE 1 Scale Employed for Weighing the Patient in Bed

vates the patient in a hammock above the level of the bed (Fig 2). This type of scale promises to prove helpful in dealing with sick patients. Weighing scales, like other apparatus, may go out of order and periodic checks for accuracy are imperative.

EXCHANGES BETWEEN THE INTRACELLULAR AND EXTRACELLULAR FLUID COMPARTMENTS

Hastings and Eichelberger¹⁸ observed that liberal amounts of normal saline solution injected intravenously into dogs caused a 48-gm gain per kilogram of muscle, detectable an hour after completion of the injection. Over the short interval during the postoperative period, when the weighing scale is being employed to gauge the status of hydration, the error introduced, by assuming that observed changes in body weight represent differences in body hydration, is probably small indeed. The basal caloric requirements of the patient after operation are almost met by the daily intravenous administration of 3000 to 3500 cc of 10 per cent glucose solution. And the urinary nitrogen loss under these circumstances is ordinarily not large, especially when small amounts of plasma are given intravenously each day in an attempt to cover the protein demands of the body.

If the surgeon is relying principally on changes in the hemoglobin to afford the same orientation, it is obvious that this method is by no means so delicate as the weighing scales. A change of 1 gm in the hemoglobin from a previous determination of 13.5 gm suggests a 7.5 per cent alteration in hydration—a figure that is synonymous with severe dehydration or overhydration. Fluctuations of hemoglobin determinations in the normal patient in the range of 5 to 10 per cent are frequent enough in the experience of clinicians to suggest that adjudication of the status of hydration by changes in hemoglobin is not reliable, especially in detecting early or lesser variations in hydration. And it is just such early departures from the normal that the surgeon should be apprised of in following the status of hydration of his patient in an intelligent manner. It is fair to suggest that the weighing scale is probably twenty-five to fifty times more sensitive than the hemoglobin determination in the detection of minor changes in body hydration in postoperative patients.

In addition to the circumstance of greater accuracy over other available methods in determining the status of hydration, the weighing scale has the advantage of simplicity. Its chief virtue lies, however, in affording a prevision of what will happen

if abnormal losses or increases in body weight are not avoided.

Why have clinicians not adopted this earlier to aid them in ascertaining the status of hydration of their patients? When will the weighing of cardiac patients become standard practice as a guide to therapy? In how many patients with urinary obstruction is the uremia observed after transurethral resection in reality extrarenal, owing to disorientation on the part of the surgeon attempting to regulate fluid and electrolyte balance? Such patients as a group, because of their age and debility, are probably especially susceptible to error in fluid therapy. Certainly, postoperative uremia is frequently observed among patients who were uremic prior to operation. Is this circumstance inherent in the disease process, or is it a complication of therapy?

It is a frequent weakness to ask others to do what we might do better for ourselves. To this frailty, surgeons are no exception. We could weigh our patients, gaining thereby first-hand information relative to the status of hydration. But the laboratory will do this for us. We could examine the patient ourselves, but a note in the consultation basket to the medical staff will accomplish that objective more readily. We could make our own diagnoses, but why bother when we have roentgenologists and pathologists to make them for us? Have surgeons improved their technic by this sluggish indifference to some of their own important problems? When will they awaken from their torpid lethargy to a realization that they alone can significantly influence their own development? Other medical specialists are too occupied with their own problems to take a vital interest in ours. It is time that we grasp the necessity of helping ourselves out of some of our own difficulties. General recognition of the value of weighing patients will help the surgeon in his wrestle with the problem of hydration. Moreover, it is probably the best instructional agency in making a staff of both surgeons and nurses conscious of hydration. Of course, in many cases this extra labor is unnecessary. But who knows when this information will be at a premium? And who counts the cost of labor when lives are at stake? The time will certainly come when weighing patients will be as much a part of hospital procedure as taking the patient's temperature. Only time and patience, however, can overcome so powerful a force as the apathy of inertia.

Technic With the adoption of early ambulation of postoperative surgical patients as a frequent practice, most patients, on the day following operation, — even after major abdominal procedures, — are asked to stand on an ordinary portable scale brought to the bedside. Until recently, when patients returned from the operating room, they were lifted onto a Red Cross litter carrier, placed on an elevated block or platform on the same type of

It is unwise to permit patients to struggle unduly during the waking period. I have the impression that patients with poor cardiac reserve often do not tolerate such struggling. I have seen at least one case—that of a patient with an antecedent coronary thrombosis—in which violent, uncontrolled struggling for a few minutes during the waking period was followed by sudden death. In any case, such violent exertion on the part of a semiconscious patient is productive of no good. When this circumstance arises, our nurses are instructed to give a small dose of Pentothal through the tubing leading to the ankle vein, into which the intravenous drip glucose solution begun at the commencement of the operation is still running. Such postponement of waking lessens the excitement of recovery from the effects of the anesthetic and affords the nurse time to cover the oncoming pain with a suitable dose of narcotic.

Regurgitation into the lungs is the most frequent cause of pneumonia whether such fluid comes from the stomach or is aspirated into the lungs from secretions in the mouth during the early phase of the recovery period.²² Keeping the stomach empty during and after operation by suction applied to an indwelling duodenal tube is therefore essential. Moreover, this practice is the best prophylaxis against intestinal distention, which frequently attends abdominal operation. The avoidance of distention and continued elevation of the legs above the level of the heart, together with active leg motion by the patient for the first few days during the recovery period are important items in the return of venous blood from the lower extremities and in preventing venous stasis and thus helping to thwart the formation of thrombi in the leg veins and their propagation as emboli.

Early ambulation of patients after operation quickens recovery and lessens the length of hospital stay. Recovery without complication is compounded of satisfactory preparation of the surgeon and the dissection and the care of the patient before and after operation. Simultaneous performance of multiple operations, such as gastric resection, cholecystectomy and appendectomy or gastric resection and partial colectomy, is well tolerated if nothing is left to chance in any part of the operative procedures. A smooth convalescence is synonymous with recovery and permits early dismissal from the hospital. It is not unusual for patients to leave the hospital five days after a gastric resection when the precepts of a well conducted operative procedure have been observed.

SUMMARY

The safe conduct of the patient through operation demands proper preparation of the surgeon, careful and precise preparation of the dissection and evaluation of the patient's condition for operation, including satisfactory preparation for the operative

procedure and watchful and intelligent care and observation through the convalescent period.

In the evaluation and maintenance of a proper fluid and electrolyte balance during the recovery period, the importance of the weighing scale is emphasized. It is believed that the routine weighing of patients undergoing major operative procedures that require the parenteral administration of fluid will materially reduce the incidence of errors in fluid therapy. In the early detection of deflection from the normal status of hydration, the weighing scale is probably twenty-five to fifty times more sensitive than changes in the hemoglobin in pre-empting the occurrence of threatening disaster to the patient occasioned by unwise administration of fluid and electrolytes. A method of weighing patients in bed after operation is described.

The success of operative procedures is a blend of many things, sovereign among which is a consecrated devotion to his tasks by the surgeon, together with a capacity for detection and critical analysis of the source and accountability of errors.

operation is poor. My associate, Dr R L Varco,²⁰ has made a special study of the preparation of such patients for operation, and the lessons learned in this clinic regarding adequate preoperative preparation may prove helpful to others. What the proper feeding of such starved and debilitated patients will accomplish is sometimes difficult to believe. A bed-ridden patient who can scarcely sit or stand may, with proper preoperative feeding, be rehabilitated to withstand severe operative ordeals. The extent of the weight loss is, in the main, the best criterion of the length of preoperative feeding period. Patients without pyloric obstruction may be fed with the intragastric drip of a feeding mixture rich in protein and carbohydrate and low in fat (the Varco II diet)

vitamin prior to operation. Vitamin K, in the preparation of patients with obstructive jaundice, has been a great boon in doing away with the hazard of postoperative bleeding in such cases. Poor-risk patients being prepared for major operative procedures, as well as in the early postoperative period, are given daily with the intravenous fluids an ampoule of crude liver extract (Campolon) and 100 mg of vitamin C. No attempt has been made to repair other likely coexisting vitamin deficiencies.

SPECIAL POSTOPERATIVE PROCEDURES

The employment of inhalation anesthesia has been standard practice in our clinic. The importance of the careful handling of an unconscious patient can

FIGURE 2 The Scale in Use

The motor on the platform (Fig. 1) has elevated the patient above the level of the bed. Neither the administration of intravenous fluid nor the suction applied to the indwelling duodenal tube is disturbed.

If a patient is able to eat, he may drink the mixture or take it through a sipper.²¹ For patients with pyloric obstruction, the preoperative preparation must be accomplished by the intravenous feedings of amino acids, plasma and glucose. Obviously, the oral route permits a more adequate and satisfactory preoperative preparation. Yet we have found preliminary enterostomy for feeding purposes unnecessary in the presence of pyloric obstruction, intravenous feeding sufficing to permit a one-stage operation.

VITAMINS

Studies on the poor healing quality of tissues in patients with vitamin C depletion suggest that all poor-risk patients be given adequate amounts of the

not be overemphasized. He should be conveyed from the operating room in moderate Trendelenburg position to encourage the gravitation of tracheal mucus or fluid into the pharynx, where it may readily be aspirated. Until the patient is wide awake and can deal satisfactorily with secretions that accumulate in the mouth, it is essential to provide for their removal. The use of a moderately steep Trendelenburg position during the waking period and an electric-suction device, operated by an experienced nurse oriented in the problems of the hazards of aspirated oral secretions, meets the needs of the situation. Intelligent bedside nursing care is a vital desideratum in the safe conduct of a patient through a major operative procedure.

ptic ulcer, 19 cases; carcinoma of lung, 16 cases, carcinoma of stomach, 16 cases, pulmonary tuberculosis, 15 cases, suppurative meningitis, 13 cases, cirrhosis of liver, 11 cases, carcinoma of prostate, 10 cases, carcinoma of bladder, 10 cases, and carcinoma of breast, 10 cases

About 50 per cent of the deaths occurred on the medical service, 35 per cent on the surgical and 15 per cent on the pediatric. The deaths were obstetric in only 1 per cent. Patient days in the hospital were distributed in about equal proportion

TABLE 1 *Data on Admissions, Deaths and Autopsies at Mary Hitchcock Memorial Hospital (1932-1944)*

DATUM	MALES	FEMALES	TOTALS	RATIO OF MALES TO FEMALES
Admissions	17,775	22,551	40,326	0.8
Deaths	812 (4.75%)	547 (2.63%)	1,359 (3.36%)	1.5
Autopsies	653	438	1,091	1.5

between medical and surgical cases, which together comprised about half the total. Pediatric cases accounted for 15 per cent and obstetric cases for 1 per cent of the total patient days.

A comparison of the age distribution of this group with that of all fatal cases in a large metropolitan region shows a correlation in some decades.² The percentage of deaths was highest in the first and lowest in the fifth decade in the group at the Mary Hitchcock Memorial Hospital, probably because the cases consisted solely of hospitalized patients. Infants born in the hospital contributed largely to the group of cases in which autopsy was performed in the first decade of life, accounting for nearly one tenth of the autopsies in this series.

The over-all importance of cancer as a fatal disease is indicated in this series, in which about one fifth of the deaths were due to cancer. If the cancerous diseases of the hemolymph system are grouped, they are second only to cancer of the large intestine in numerical importance.

Certain trends indicate that hospital death statistics cannot be compared with general death-certificate data. The development of special services

within a hospital is shortly reflected in the autopsy service. Changing therapies lead to increasing or decreasing hospitalization within a group. For the same reasons, comparison of data of different hospitals is difficult.

The numerical significance of such a series is so slight that the chief values of the service and analyses obviously accrue to the hospital and staff concerned. The purpose of this analysis and presentation is to emphasize the fact that, despite the lack of great contribution to general statistics, valuable information is afforded by routine autopsies to the small hospital and to medical groups that cannot be obtained in any other way.

This report includes only the data accumulated at the Mary Hitchcock Memorial Hospital. The consistently high percentage of examinations, however, is considered to be due in part to the program throughout the area. There has been co-operation of the small hospitals in the community, the Mary Hitchcock Memorial Hospital and the Dartmouth Medical School to achieve as high as 50 per cent of autopsies in individual small hospitals and in one physician's rural practice.³ During the period covered, autopsies have been done in and for ten participating institutions. Analysis of this series is in progress.

CONCLUSIONS

Autopsies should be a matter of routine. Only when the public is familiar with the value of autopsies will permissions be granted in a high percentage of cases.

Cases should not be selected for their "interest." Such selection defeats many of the purposes of the autopsy.

Autopsy statistics are of little value as statistics unless a high percentage of deaths are followed by autopsies that are routine.

Autopsies done in a high percentage of cases yield many valuable data not obtainable otherwise.

AUTOPSY SERVICE AT THE MARY HITCHCOCK MEMORIAL HOSPITAL*

RALPH E. MILLER, M.D.†

HANOVER, NEW HAMPSHIRE

IN 1932 the Mary Hitchcock Memorial Hospital staff established standard autopsy procedures that have led to a consistently high percentage of permissions for post-mortem examination. The essential features of the program are as follows:

A hospital staff that agrees that all deaths be followed by a request for post-mortem examination. Precedence is given to the obtaining of permission for autopsy because of the fleeting nature of the opportunity to give a valuable service to the family of the deceased — I have never known a family to be antagonized by a request for autopsy.

A department of pathology ready to perform an autopsy at any hour of the day or night required by the circumstances. The effort required of the physician to obtain permission justifies an equal effort on the part of the pathologist to avoid delay and secure fresh material.

A public that is informed concerning the value of autopsy. Discussion of the facts of the case, particularly at the time immediately following autopsy, gives the pathologist an opportunity to answer many questions that, if left unanswered for long, may leave relatives in a puzzled frame of mind and cause them to seek the answers elsewhere. Following such an interview, the relatives are referred to the family physician, to whom a final complete report is sent.

A co-operative group of funeral directors. Frequent contact is required to determine possible improvements in technic or schedule and thus to avoid interfering with the funeral director's obligations to the family.

The continuity of the program is maintained by presenting to each new member of the staff the following statement:

An Approach to Securing Autopsy Permission

Autopsy percentage will be considered satisfactory when it reaches 100 per cent. Autopsies are done only after permission of the nearest relative or responsible person has been obtained, preferably by interview. It is important that relatives be aware of the following features of the autopsy service:

- 1 Autopsies are made without charge at considerable expense to give all concerned valuable information not otherwise obtainable.
- 2 Autopsies are done discreetly in such a manner as to avoid disfigurement of the body so far as the funeral is concerned. The method of autopsy makes better embalming possible for a competent embalmer.
- 3 Relatives should be assured that autopsy does not necessitate delay.

The purpose of the program was to approach as nearly as possible complete analysis of all hospital deaths. The results have been encouraging. Autopsies had been done in the region by medical school physicians for many years — the percentage during those years is not a matter of record, but was certainly low. Interest in autopsies, even without a formal program, resulted in an increase from less than 10 per cent (estimated) in 1926 to about 60 per cent after three years. The rise in the curve from this 60 per cent plateau followed the agreement of the staff members concerning the program and their complete co-operation in carrying it out.

In the twelve-year period 1932-1944, the Mary Hitchcock Memorial Hospital admitted a total of 40,326 patients. Figure 1 presents the autopsy

FIGURE 1. Curve of Percentages of Autopsies in Relation to Deaths (Mary Hitchcock Memorial Hospital, 1926-1945).

percentages. Table 1 indicates the sex distribution of patients admitted, patients dying in the hospital and patients autopsied. This distribution suggests that permission for autopsy is obtained with the same ease whether the patient is male or female. House¹ has analyzed and published elsewhere the data concerning most of these cases. The principal causes of death, exclusive of stillbirth, in 488 cases of the series of 1091 autopsies were as follows: hypertensive cardiovascular renal disease, 85 cases; coronary-artery sclerosis, 57 cases; rheumatic heart disease, 51 cases; carcinoma of large intestine, 46 cases; suppurative appendicitis, 32 cases; lobar pneumonia, 28 cases; pulmonary embolism, 25 cases; benign hypertrophy of prostate gland, 24 cases; subacute bacterial endocarditis, 20 cases;

†Professor of pathology, Dartmouth Medical School; director of laboratories, Mary Hitchcock Memorial Hospital.

In an earlier series of cases no systemic, toxic or allergic manifestations were observed²²⁻²⁴. More recently, however, we have noted local and generalized manifestations consisting of edema of the lips, the mucosa of the mouth and, in several cases, a generalized urticaria. The local reactions generally subsided after a change to another type of penicillin. In the urticaria in 1 case cleared up promptly when treatment ceased and did not return when a different type of penicillin was used. In a recent case with complicating urticaria we were able to continue with the same lot of penicillin by adding oral benadryl, this new synthetic antihistamine agent as apparently of value.

The apparatus used in our studies was the basic vaponefrin nebulizer* enlarged to a capacity of 2 liters to permit the utilization of the expired penicillin. This nebulizer produced a fine, voluminous mist or smoke screen with a particulate size of less than 1 micron. A piece of rubber tubing connected the nebulizer with a regulator attached to an oxygen tank. Oxygen flows of 5 to 7 liters were usually sufficient to aerosolize 10 cc of the penicillin solution in approximately fifteen minutes. To avoid loss of the drug in expiration, a glass Y tube was placed just proximal to the inlet of the nebulizer. The patient or nurse was instructed to close the open end with a finger during most of the inspiratory cycle and to remove the finger at the end of inspiration and during the entire expiration. With this technic the oxygen bypassed the nebulizer in the expiratory phase of respiration and no appreciable penicillin was lost through the top carburetor opening of the nebulizer. In the severest cases an automatic device perfected by Emerson delivered the penicillin aerosol during the inspiratory cycle by modifying a demand-type oxygen regulator. The lowering of pressure within the nebulizer at the start of inspiration released from the demand valve a flow of oxygen that then passed through the nebulizer. The penicillin aerosol in this technic was thus formed only on inspiration and did not require the co-operation of the patient. We recently modified our technic by attaching an Ohio humidifier directly to the regulator. The humidifier may be filled with hot tap water, which seems to add to the comfort of the patient. We are making further studies to determine whether it diminishes the occurrence of local reactions in the mouth and lips.

The nebulizer may be suspended or attached to a clivus stand for patients too sick to hold it themselves. We have found, however, that the majority of patients can comfortably hold the apparatus during the fifteen or twenty minutes of treatment. It is also advisable to have the nurse add 0.25 or 0.5 cc of physiologic saline solution at the end of the last daily treatment to clean out the nebulizer and to prevent further deposition of penicillin in the delicate horizontal and vertical rods of the apparatus.

*Obtainable from Vaponefrin Company, Upper Darby, Pennsylvania.

For patients who are unable to use the technic described above, the OEM mask can be employed. The nebulizer can be introduced into the face piece of the mask, and the oxygen entrance closed off. Infants and small children can best be treated in enclosed plastocene hoods or in specifically constructed closed chambers, the basic nebulizer and oxygen flows described above being used.

The basic Vaponefrin nebulizer can also be attached to the tracheotomy tube whenever topical penicillin aerosol therapy is desired in tracheotomy cases. We have found this of particular value in 2 patients with acute laryngotracheobronchial edema characterized by marked cyanosis and inspiratory retraction. These patients were moribund at the beginning of therapy. In these patients, instead of using oxygen, we have employed a mixture of 75 per cent helium and 25 per cent oxygen, introducing this mixture directly through the nebulizer. This technic may prove to be of lifesaving value in patients with laryngotracheobronchial obstructive disease.

Barach and his associates¹³ devised an apparatus for the introduction of penicillin aerosol into the nasal accessory sinuses following suction. We²⁵ employed this apparatus in a series of 24 patients with infective sinus disease and found it extremely efficient.

Prigal and Speer²⁶ recently described a method of aerosolizing penicillin by the use of steam in place of oxygen flows. This procedure may be of value in infants and children with infective croup, and the aerosol can be directed into the oxygen tent if humidification is particularly desirable.

PENICILLIN BLOOD LEVELS

Absorption of penicillin from the pulmonary tree into the blood stream was demonstrated by effective penicillin blood levels, which ranged from 0.015 to 0.225 units per cubic centimeter in one hundred and sixteen determinations (Fig 1). Large doses resulted in higher levels than did smaller doses, and the levels after crystalline† penicillin were higher than those after corresponding amounts of amorphous penicillin. Generally higher blood levels were obtained in patients with extensive lung involvement of a pyogenic type — that is, with pneumonia or lung abscess. Peak levels, which were observed at the end of thirty minutes, in some cases persisted for as long as two hours. The absorption of penicillin into the blood stream is not necessarily a measure of the topical effectiveness of penicillin aerosol. The blood levels vary according to the individual breathing pattern, equipment, dosage and type of penicillin, absorption variations of accumulated pus and secretions and the technic employed in the determination. In most of the cases the determination of blood levels is more of academic interest than of practical value. The clinical course is sufficient proof of the topical effectiveness of peni-

PENICILLIN INHALATION THERAPY*

MAURICE S SEGAL, M D, † AND CLAIRE MACINTYRE RYDER, M D ‡

BOSTON

INHALATION therapy has attained amazing prominence since the ancient and empirical practice of inhaling medicated vapors. In a report on the use of oxygen, helium and oxygen mixtures and aerosolized sprays of various therapeutic agents for the maintenance of respiratory function, the use of penicillin aerosol was suggested.¹ Barach and his associates^{2, 3} first described the technic and the value of continued vaporization of various drugs with oxygen streams. Castex et al,^{4, 5} Krueger et al,^{6, 7} and Mutch⁸ demonstrated that aerosolized substances penetrate to the outermost air sacs of the lungs and to the ends of the bronchial tree.

The physiologic rationale of penicillin aerosol therapy has been well established. Bryson et al⁹ demonstrated that penicillin aerosol penetrated the lungs, diffused into the blood stream and was excreted in the urine. Barach and his associates¹⁰⁻¹⁴ confirmed these observations in a group of patients with bronchopulmonary disease and developed the proper equipment and technic for penicillin aerosol therapy. In a detailed investigation of the fate of aerosols in the lungs, Mutch and Rewell¹⁵ further proved the efficacy of the therapy. They suggested the use of penicillin aerosol in the management of purulent bronchitis and bronchiectasis and as a prophylactic against secondary pyococcal infection in influenza. Knott and Clark¹⁶ carried these studies farther, demonstrating effective bacteriostasis in closed chambers and suggesting a technic for the control of airborne infections. Other investigators¹⁷⁻²¹ have employed penicillin aerosol with encouraging results in the management of pulmonary infections. In most cases effective therapeutic blood levels and excellent topical effects have been obtained.

This report concerns a summary of our findings in the use of penicillin aerosol in the treatment of 85 patients with bacterial pneumonia, suppurative bronchitis, bronchiectasis, lung abscess, infective bronchial asthma, infective laryngotracheobronchial edema, chronic pulmonary emphysema and emphysematous blebs.

TECHNIC

The control of infection by penicillin is dependent on the susceptibility of the bacteria, the resistance of the strain responsible for the infection, the dura-

tion of exposure of the organism to an effective local concentration of penicillin and the attainment of an adequate concentration of penicillin in the blood to penetrate the dense inflammatory foci in which the bacteria are embedded, the maintenance of such a constant high level is not essential in purely local pulmonary infections without bacteremia. Topical penicillin levels can be attained by the administration of concentrated doses six times daily. In patients with toxemia or septicemia additional intramuscular doses, five or six times daily, may help in producing blood levels sufficiently high to clear the blood stream of bacteria. Infections of the lung, which usually occur in well vascularized soft tissues, generally respond to concentrations of penicillin that are completely ineffective in the relatively avascular hard tissues.

The patients with pneumococcal pneumonia were treated for three to seven days, those with bronchiectasis or lung abscess, for seven days prior to surgery or for six weeks for purely medical therapy, those with infective bronchial asthma, from three days through three weeks, and those with streptococcal or staphylococcal pneumonia complicated by abscess formation, generally for a minimum of three or four weeks. The other patients were treated until there was no further evidence of infection and the penicillin-susceptible organisms had been eradicated.

The sodium or calcium salt of penicillin was used. Generally 25,000 units of penicillin were dissolved in 10 cc of physiologic saline solution and given at three-hour intervals for six to eight doses daily. The patients with pneumococcal pneumonia and those with acute or chronic sinusitis generally received 25,000 units at two-hour intervals for six doses and at three-hour intervals thereafter. The patients with the more serious types of pneumonia and lung abscesses received 50,000 units in 20 cc. of physiologic saline solution. These patients were able to take with complete tolerance 50,000 or even 100,000 units by the nasal route.

The calcium salt was less irritating but was usually more difficult to obtain than the sodium. The ampoules containing 200,000 units were of more practical value. Many patients objected to the taste and smell of the penicillin aerosol or found it irritating to the tongue or oropharynx. These complaints were minimized by a change to other lots of penicillin. A few patients developed sore tongues or stomatitis following the therapy. Saline rinses, dental hygiene and frequent sips of water during the treatment helped to diminish these complaints.

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 21, 1946.

advisable to ensure complete eradication and to prevent exacerbations and abscess formations. To control pneumonia due to penicillin-susceptible strains of Friedländer's bacillus we have employed massive doses of 100,000 units at three-hour intervals in 2 cases. In one of these patients a blood level of 250 units of penicillin per cubic centimeter was obtained thirty minutes after the inhalation of 30,000 units. In both cases the organisms rapidly disappeared, remaining absent in one case during the course of therapy, in the other, however, the organisms recurred, although the patient remained symptom free for some time after the discontinuance of therapy. The patients with pneumococcal pneumonia required treatment for three to seven days. All were cured, with no ensuing complications, and they were generally discharged between the sixth and the eighth day after hospitalization. A brief abstract of a recently treated case of pneumonia follows.

A 28-year-old man entered the hospital with a complaint of pain in the right side of the chest of 4 days' duration. Two weeks prior to entry he had complained of a cough, productive of white frothy sputum. Examination revealed an acutely ill man. The temperature was 102°F. X-ray examination of the chest disclosed a typical pneumonia in the right upper lobe. Sputum culture revealed a Type 2 pneumococcus.

On admission a course of penicillin aerosol was started as follows: 50,000 units every 2 hours for six doses followed by 50,000 units every 3 hours until a total of 1,000,000 units had been given and, finally, 25,000 units every 3 hours, omitting the 3:00 a.m. dose daily. The temperature dropped to normal within 48 hours and remained essentially normal thereafter. A total of 2,115,000 units of penicillin was given over a 9-day period. Recovery was complete, and the clinical chart was similar to that in other cases previously reported.

INFECTIVE BRONCHIAL ASTHMA

A course of penicillin aerosol lasting from three days to three weeks was given to 22 patients with severe chronic infective bronchial asthma. The penicillin-susceptible organisms promptly disappeared and in most cases remained absent during hospitalization. This therapy was generally disappointing, although striking improvement was occasionally observed. In these patients control of the primary bronchial infection with intramuscular penicillin and oral sulfonamides has proved equally disappointing. Most of the patients observed, however, that they were able to raise sputum more easily while receiving penicillin aerosol. Many objected to the taste and the irritating qualities of the aerosol. The danger of local or generalized allergic reaction to penicillin aerosol in asthmatic patients must always be kept in mind. Most of the local and urticarial reactions observed occurred in patients with bronchial asthma or bronchiectasis.

A striking remission was observed in a patient with chronic intractable bronchial asthma who was treated in the Barach rebreathing hood apparatus with mixtures of 75 per cent helium and 25 per cent oxygen under positive pressure. In addition, penicillin aerosol was introduced directly into the hood

apparatus. Marked clinical improvement occurred after several days of such therapy. It was difficult, however, to evaluate the specificity of penicillin aerosol therapy in this case, for similar observations have been made in many patients treated with helium and oxygen under positive pressure without penicillin aerosol.^{23, 29}

BRONCHIECTASIS

A series of 30 patients with chronic bronchiectasis were treated with penicillin aerosol. Most of these patients received an initial course of therapy of at least six weeks and subsequently returned for an additional seven to ten days of therapy at intervals of three to six months. Postural drainage was carried out immediately before each treatment. Several of these patients continued to take penicillin aerosol therapy once daily at home throughout this period, this procedure was effective in preparing the patient for surgery and in preventing post-operative infections. Defervescence, lessening of toxicity, diminution in the amount of daily sputum, loss of its foul character, rapid disappearance of the penicillin-susceptible organisms, improvement in the patient's appetite and gain in weight were uniformly observed. Considerable improvement occurred in the bronchograms of several patients with involvement of a single lobe. This therapy was most helpful in the control and prevention of pneumonitis, which recurs in many patients with bronchiectasis. It was also of value in patients who were considered to be unsuitable for lobectomy or pneumonectomy or who refused to undergo such procedures. We are ever mindful that the anatomic changes accompanying bronchiectasis are permanent and cannot be altered by any type of therapy except resection. These patients are subject to repeated episodes of infection, pneumonitis or involvement of other lobes. The mucosal secretions in bronchiectasis largely result from the structural changes in the endothelial lining of the smaller bronchioles. Invasive organisms contribute by further destruction of the bronchioles. Infection can be eradicated or eliminated by penicillin aerosol, which thus provides the ideal therapy for preoperative and postoperative cases.

Many patients had previously received courses of intramuscular penicillin and oral sulfonamides without the striking effects obtained from penicillin aerosol, which effected longer periods of freedom from symptoms and recurrence of pneumonitis than other forms of therapy. The vital capacities of most of these patients increased from 30 to 40 per cent above the levels before aerosol therapy and remained fairly constant at the improved figure. Penicillin aerosol treatment can easily be carried out in the patient's home under supervision.

The penicillin-susceptible organisms uniformly disappeared from the sputum under such therapy. The appearance of gram-negative organisms, however, was observed in many patients who had been

cillin aerosol and is best demonstrated in patients with pneumonia

It was considered advisable to study the penicillin blood levels* in a series of 6 normal medical students receiving penicillin aerosol by the pulmonary route (Table 1) Inhalations of 50,000 units of sodium penicillin in 10 cc of physiologic saline solution were given with the technic described above Blood levels were obtained thirty minutes, one hour and two hours after the beginning of each treatment Similar studies were later performed on the same group,

peutic agent that could achieve greater topical efficacy and less systemic effect would prove of considerable value in combating chronic pulmonary disease

PNEUMONIA

Observations in this group of patients definitely proved the efficacy of penicillin aerosol in combating bacterial pneumonia and may serve as the rationale for its subsequent use in suppurative pulmonary disease Clinical cures were obtained in 9 patients with pneumococcal pneumonia and in 1 with an acute pulmonary infarct and pneumonitis The case histories and clinical charts of 6 of these patients were presented in an earlier report²¹ Blood levels of from 0.028 to 0.055 units per cubic centimeter were observed in 7 cases in which 25,000 units of penicillin had been administered Levels as high as 0.250 units per cubic centimeter were obtained when 50,000 units were employed in 2 other patients We

FIGURE 1 Average Penicillin Blood Levels following the Inhalation of Penicillin Aerosol

1.0 cc of 1 per cent Neosynephrine being substituted for the saline solution The average figures obtained with penicillin-Neosynephrine aerosol appeared lower than those obtained with penicillin-saline aerosol, particularly after thirty minutes and one hour This may be interpreted as indicating that Neosynephrine delays the absorption of penicillin through the pulmonary tree In vitro studies have demonstrated that penicillin fully retains its potency in solutions of Neosynephrine for as long as twenty-four hours²⁷ We are repeating these studies, employing 100,000 units in the same subjects, since a thera-

do not advocate penicillin aerosol for the routine therapy of patients with pneumococcal pneumonia, the simpler procedures employing the sulfonamides or penicillin are preferable For the management of pneumonia due to streptococcal, staphylococcal and penicillin-susceptible strains of Friedländer's bacillus, penicillin aerosol therapy is probably more effective than parenteral therapy alone Combined aerosol and intramuscular therapy may be employed in patients who are seriously ill, particularly those with septicemia For patients with staphylococcal pneumonia the therapy should be continued for at least a week after all the clinical and roentgenographic signs of infection have subsided Since the lesions tend to become fibrosed and walled off, protracted therapy

*This work was aided by a grant from Frederick Stearns and Company

aerosol was then resumed for 10 days, at the end of which chest film revealed no evidence of the cavity and only light residua of the lipiodol. The patient was then discharged symptom free.

ACUTE LARYNGOTRACHEOBRONCHIAL EDEMA

Six patients with laryngotracheobronchial edema associated with serious infection were treated with penicillin aerosol, constant streams of oxygen or mixtures of 75 per cent helium and 25 per cent oxygen being employed. These patients were moribund at the outset of therapy. The conventional methods of employing sulfonamides, parenteral penicillin and oxygen therapy by catheter, mask and tent had been tried with little benefit. Dramatic improvement was observed as soon as the inhalation program was instituted. It was the opinion of many observers that the recovery of these patients could be directly attributed to the above therapy. A brief abstract of a recently treated case follows.

A 56-year-old man gave a history of aphagia and progressive inspiratory dyspnea of 14 hours' duration. He was found sitting up in bed struggling for breath, with marked inspiratory stridor and some prolonged expiratory wheezes through both lung fields. The temperature was 102°F. The lips were cyanotic, and the patient appeared critically ill. He had inhaled considerable dirt and dust while attempting to clean an attic. After several hours of exposure he began to cough, raising blood-streaked sputum, and noticed some shortness of breath. A few hours later he was found in a state of collapse. Oxygen and aminophyllin were administered, with little effect. Tracheotomy was being considered immediately before we first saw the patient. His wife stated that he had an extensive history of hay fever and seasonal bronchial asthma but had been free of asthma for several years and had complained of but minimal hay fever while undergoing hyposensitization injections. He had also shown marked positive reactions to molds and dust. An aural consultant had found extensive edema of the fauces and larynx.

Inhalation therapy, consisting of 75 per cent helium and 25 per cent oxygen through the O.E.M. positive-pressure mask, was instituted at once. At the same time 25,000 units of penicillin were introduced directly into the face piece with the Vaponefrin nebulizer. Treatments were given at 3-hour intervals. Inhalations of helium and oxygen mixtures with the mask set at 2.0 or 4.0 cm. of positive pressure were carried out for ½ hour out of each hour. Supplemental intramuscular aminophyllin was administered from time to time. Preceding each penicillin aerosol treatment, inhalation of 10 cc Vaponefrin was introduced directly into the face piece. Improvement was striking from the beginning of therapy. The faucial and laryngeal edema subsided slowly and cleared entirely within 3 days, the respiratory stridor disappeared after 12 hours, the attacks of bronchospasm and coughing being easily controlled with the Vaponefrin inhalations, and the temperature returned to normal after the 2nd day. There were no complications, and recovery was complete on the 6th day of treatment.

PULMONARY EMPHYSEMA AND EMPHYSEMATOUS BLEBS

Patients with chronic pulmonary emphysema generally present a history of cough, progressive dyspnea even at rest, weight loss and weakness. Many develop severe clubbing of the fingers and cyanosis, in a few cases severe emphysematous blebs are present. Bronchiectasis and evidence of bronchospasm may also be found in many cases. The patients are subject to recurrent bouts of respiratory infections, and their pulmonary reserve diminishes with each bout. The prognosis is generally poor

and progressive respiratory failure develops. The patient can be made more comfortable with the use of 50 per cent concentrations of oxygen, aminophyllin and aerosolized bronchodilator drugs. Supplemental elevation of the diaphragms by manual manipulation in expiration and the use of a proper abdominal belt may be of considerable value. Oral sulfonamides have proved of little benefit in the prevention of recurrent infection.

We have recently observed striking improvement in a series of 6 patients with severe pulmonary emphysema when penicillin aerosol was added to the program described above. In one of these patients diffuse emphysematous blebs and a minimal basal bronchiectasis complicated the picture. In another a giant acquired cyst occupied the entire upper lobe of the right lung. The remaining 4 patients had uncomplicated pulmonary emphysema secondary to recurrent bronchial infections. These patients were considerably improved after a course of penicillin aerosol therapy of from one to six weeks. They had been treated with oxygen and bronchodilator drugs first but had developed more progressive dyspnea, cyanosis and cough. After penicillin aerosol administration the vital capacities improved slightly, and this improvement was maintained at home while the therapy outlined above was being continued. These remissions have been striking, although probably temporary.

We believe that all patients with severe pulmonary emphysema who fail to improve with treatment employing the principles discussed above should receive a course of penicillin aerosol therapy. A typical case history follows.

A 72-year-old physician complained of progressive cough and dyspnea of 6 years' duration. During the previous year the cough had been productive of 120 or 150 cc of whitish, mucoid sputum daily. He had received two intensive courses of intramuscular penicillin and a course of oral sulfonamides without clinical improvement. Examination of the lungs revealed diminished breath sounds, coarse moist rales at the bases and marked hyper-resonance throughout. A chest plate revealed severe pulmonary emphysema, blebs and minimal basal bronchiectasis. The vital capacity was 1800 cc. The patient was advised to restrict his activities, to wear an abdominal belt and to take Adnefrin capsules and inhalations of Vaponefrin. On this program he improved remarkably and was soon able to resume most of his activities.

He continued these activities without many complaints for 10 months, when he acquired an upper respiratory infection and the earlier symptoms returned. The dyspnea soon became severe, and cyanosis appeared for the first time. The amount of sputum increased to about 300 cc. daily and cultures revealed many alpha-hemolytic streptococci and *Aerobacter aerogenes*. The cough was harsh and paroxysmal. During these paroxysms the cyanosis became marked, and the respiratory rate rose to 30 to 40. The patient was acutely ill on admission.

A program of inhalation therapy was instituted as follows: intermittent use of the oxygen tent and oxygen sprays of Vaponefrin at 3-hour intervals, followed by 25,000 units of penicillin aerosol for six daily doses. The clinical course was stormy during the first 2 days. Paroxysms of coughing and obstructive breathing frequently occurred and on several occasions death from suffocation appeared imminent. Gradually, the cough became less severe and productive of thinner mucoid material. The respirations and pulse fell progressively to the high normal ranges. The pathogenic organisms disappeared from the sputum. At the end of 8 days of treat-

refractive to penicillin aerosol. A recent report by Olsen¹⁸ favored the use of streptomycin aerosol in such patients. He employed doses of 500,000 units a day by nebulization and reported negligible urine and blood levels. The streptomycin-susceptible organisms were uniformly eradicated, and favorable results were obtained in most cases. Our experience with streptomycin aerosol has been limited to 2 patients with Friedländer organisms. In our first trial with this drug the streptomycin-susceptible organisms rapidly disappeared when 100,000 units at three-hour intervals were employed but returned after several days of therapy. We then found it necessary to increase the dose. After a while the organisms became more resistive and could not be eradicated despite tremendous doses. The possible appearance of streptomycin-resistive strains with aerosol should be taken into consideration before such treatment is initiated. Barach has also called my attention to one of his patients who developed involvement of the eighth nerve, with ataxia, following the use of parenteral streptomycin therapy. It appears from the literature that streptomycin may prove of value in selected cases of pulmonary infection due to Friedländer, influenza or tubercle bacilli and that combined intramuscular and aerosol therapy may be efficacious in such cases. The practical usefulness of the drug, however, may be limited by its toxicity, the development of resistive strains and its cost.

A group of patients with sinus involvement either preceding or associated with bronchiectasis required special attention.²⁵ A number of these patients were treated with penicillin aerosol by the nasal route, suction being employed before the positive-pressure aerosol. The suppurative sinus disease was adequately controlled in most of these cases. The combination of sinusitis and bronchiectasis was found most difficult to treat adequately. The percentage of recurrences of active sinusitis and bronchiectasis has been higher in this group than in patients with uncomplicated bronchiectasis. Proper drainage and pressure therapy are important adjuncts to penicillin aerosol therapy by the nasal route in the management of acute and chronic purulent sinus disease. We consider this approach most valuable in the management of sinus disease and are indebted to Barach and his associates¹³ for the development of the proper equipment.

A brief abstract of a recently treated case follows:

A 45-year-old woman entered the hospital complaining of a productive cough, fever and malaise of 1 month's duration. During the previous 7 years she had had frequent bouts of fever, chilliness, chest pain and a productive cough, lasting for several weeks at a time. Between attacks she had remained well. Three years previously a diagnosis of bronchiectasis of the lower lobe of the left lung had been made by a lipiodol bronchogram. During each of the recent bouts a course of sulfonamides had been given, with good results. After several days of such therapy the infectious process (pneumonitis) usually subsided rapidly and recovery was fairly complete in 1 to 3 weeks.

The present illness started as usual with a "head cold" and was characterized by fever, cough and malaise. During the usual course of sulfonamides the sputum increased in amount to about 150 cc daily. Cultures revealed hemolytic streptococci and staphylococci. Physical examination and x-ray films revealed an atelectasis of the left lower lobe with slight retraction of the heart to the left. A course of penicillin aerosol, 25,000 units every 3 hours for six days, was started. Improvement quickly followed. The cough and sputum subsided after the 5th day of treatment. The organisms were no longer found in the sputum. The patient was greatly improved and as well as usual after 10 days of treatment.

Because of the persisting atelectasis, bronchoscopy was performed on the 11th day. The bronchi were patent throughout, and no secretions were found in the left lower lobe. Lipiodol was instilled, and the bronchogram revealed a minimal subsegmental bronchiectasis of the left lower lobe and a portion of the lingula, the entire lower lobe was considerably smaller than usual. Penicillin aerosol was continued for 3 days after this procedure, and the patient was then discharged. The therapy continued at home for a full 6 weeks' course. She had remained symptom free 3 months* following discharge.

LUNG ABSCESS

We have employed penicillin aerosol therapy in a series of 11 patients with lung abscesses. Our observations have impressed us with its value in the aerobic, nonodoriferous, postpneumonic type of lung abscess, the results with the anaerobic, putrid, atelectatic types were disappointing. Doses of 50,000 units of penicillin given at three-hour intervals were usually adequate. Postural drainage was generally carried out prior to each treatment. In the more toxic and putrid cases we employed simultaneously 25,000 units of penicillin intramuscularly. Therapy was continued for at least four weeks. With an effective program of penicillin aerosol it is possible to avoid surgery in most of these cases. In most of our cases we did not employ intramuscular penicillin along with penicillin aerosol. Clinical and roentgenologic confirmation of cure was obtained in all cases, in several cure was further confirmed by lipiodol bronchograms. A brief abstract of a typical case follows:

A 37-year-old Negro entered the hospital complaining of high fever, shaking chills and hemoptysis. Two weeks before admission he had developed a nonproductive cough, chills, the fever and pleuritic pain in the left side of the chest. The cough became productive of rusty sputum, later turned bloody and finally became rusty again, with a foul odor. The patient collapsed on the 15th day of the illness and was admitted to the hospital. He filled a box with putrid sputum during the first 12 hours in the hospital. The sputum smear revealed gram-positive and gram-negative diplococci, spirilla and fusiform bacilli. An x-ray film of the chest disclosed a pulmonary abscess opposite the left hilus.

A course of penicillin aerosol was started as follows: 50,000 units every 2 hours for six doses and subsequently every 3 hours until a total of 1,000,000 units had been given, after which the dose was reduced to 25,000 units every 3 hours, omitting the 3:00 a.m. dose. Postural drainage was carried out preceding each treatment. The temperature dropped rapidly to normal. The sputum rapidly lost its foul odor and cultures subsequently revealed *Proteus vulgaris* and also *Klebsiella pneumoniae*. The patient was permitted up and about after the 4th week.

At the end of the 5th week of continuous therapy, a shortage of penicillin occurred, and inhalations of 1 cc. of 5 per cent sodium sulfathiazole at intervals of 3 hours were substituted for a 10-day period. A bronchogram revealed a small cavity, measuring 1.5 by 1.0 cm, presumably in the lingula. Penicillin

*Now 10 months following discharge the patient is still symptom free.

MEDICAL PROGRESS

ABDOMINAL SURGERY

ARTHUR W ALLEN, M D *

BOSTON

DURING the past year many articles have appeared on the management of battle wounds of the abdominal viscera. It is not possible to do this subject justice in a general review of abdominal surgery. Doubtless, this valuable experience with abdominal wounds will be collected in a separate report and will become an authoritative contribution. Suffice it to say that the selection of well trained, up-to-date surgeons, guided by consultants experienced in teaching and practice, played an important part in the remarkably fine results obtained.

EARLY AMBULATION

Early ambulation is discussed by Blodgett and Beattie.¹ These authors made a comparative study of 238 consecutive patients with abdominal operations treated by early rising and 443 similar patients who were kept in bed seven or more days after operation. In both groups complications were expected. They followed closely the principles of early ambulation set down by Leithauser and Bergo.² First, the patient is turned on the side of the operative wound, and the knees are flexed. He is then assisted to a sitting position on the side of the bed, and the shoes are put on. He is helped to stand on a footstool and encouraged to take deep breaths and to cough. He is walked for 8 to 10 feet and allowed to sit in a chair for ten minutes, after which he is walked back to bed. This process is repeated twice daily until the patient can arise and walk unaided. The early risers had less pain in their wounds, were able to care for themselves on about the fourth postoperative day and were ready for discharge from the hospital much earlier than the patients in the control group. There were fewer cases of wound disruption and fewer pulmonary complications with early ambulation, but there was a somewhat greater incidence of thrombosis in the leg veins.

It is essential to point out that early ambulation is often not well understood by the nursing personnel and by the house staff. Patients are lifted to a chair and allowed to sit too long, which, in fact, is conducive to stasis in the leg veins. The omission of the putting on of the shoes before walking is a serious matter, since the abnormal strain on the calf muscles may produce soreness that can be mis-

interpreted as early venous thrombosis. The added burden of carrying out these maneuvers correctly is compensated for by the early resumption of self-care. That modern preparation, anesthesia, wound closure and fluid replacement make early ambulation safe and sensible is accepted. The beneficial results obtained with shorter periods of postoperative recovery, less nursing care and probably fewer complications are well worth while.

HERNIA

Haber³ suggests the use of a long, silk, guide suture, placed in healthy bowel just above the questionable segment in strangulated hernia. The loop in doubt is returned to the peritoneal cavity, and oxygen administered by mask for fifteen minutes. By gentle traction on the guide suture, the bowel is brought back into the wound for inspection. In 4 cases reported, the decision of viability was determined by this method. Doubtless, the circulation will have a better chance for restoration in its normal environment than by the usual technic of warm physiologic saline compresses on the exteriorized segment.

Fisher⁴ reports 6 cases of interstitial hernia from McBurney appendectomy incisions that were diagnosed preoperatively as inguinal hernia. The herniation had taken place through the defect in the peritoneum of the wound, and the omentum had dissected along the muscle planes to the inguinal canal, presenting at the external ring.

In 1934 Wangenstein⁵ reported the use of a large flap of fascia lata, turned cephalad and left attached at the upper end, for the repair of large inguinal and femoral defects. In a recent contribution he⁶ reports the use of this technic in the repair of large abdominal-wall defects. In 3 cases of extensive carcinoma of the bowel and in 1 with a huge dermoid tumor in which large segments of the abdominal wall had been sacrificed, the use of these large pedicle grafts of fascia lata were used successfully. One of the defects measured 24 by 18 cm. In 3 patients with upper abdominal defects, one of which measured 26 by 21 cm., repair was achieved by swinging the lower rectus fascia upward.

THE SPLEEN

Dunphy⁷ has made a timely contribution on the technic of splenectomy. He gives Balfour⁸ credit for the method used. Instead of the tedious dissec-

*Lecturer in surgery, Harvard Medical School; chief, East Surgical Service, Massachusetts General Hospital.

ment the patient was transferred to his home, where the therapy was continued. Approximately 3 weeks after admission to the hospital he was up and about, feeling comparatively well. The cough was hardly noticeable and productive of but 15 or 20 cc of sputum daily. The vital capacity was 2400 cc. This improvement was maintained for several months. We believe, however, that this recovery is probably temporary, in view of the serious underlying pulmonary disease.

DISCUSSION

Penicillin aerosol therapy is of definite value in the management of serious respiratory disease. It can be carried out best with the simple rebreathing technic described above. This may be modified, depending on the age of the patient and the nature of the illness. Helium and oxygen streams may be employed instead of oxygen for patients demonstrating obstructive respiratory disease. The penicillin aerosol may also be directed into tents, masks and tracheotomy openings. Other chemotherapeutic, antibiotic and chemical drugs may be substituted for penicillin if indicated. Finally, the penicillin aerosol may be directed nasally for the management of patients with acute and chronic purulent sinus disease.

Penicillin aerosol therapy should not be employed by the nasal or pulmonary route for the management of the common cold. This infection generally runs a self-limited course despite all so-called "useful therapy." One must always bear in mind the possibility of the appearance of penicillin-resistant strains in all cases of repeated or prolonged penicillin aerosol therapy.

This treatment should be reserved largely for patients with the following conditions: purulent sinusitis, bronchiectasis, lung abscess, infective bronchial asthma, infective bronchitis, pulmonary infections with the streptococcus, staphylococcus or penicillin-susceptible strains of Friedländer's bacillus and infections secondary to underlying primary disease of the lungs, such as pulmonary emphysema, lung cysts and infarcts. Every attempt should be made to identify the organisms from the nose, throat and sputum before therapy is begun.

SUMMARY

Observations in the management, with penicillin aerosol, of 85 carefully studied patients with bacterial pneumonia, infective bronchitis, infective bronchial asthma, lung abscess, bronchiectasis, infective laryngotracheobronchial edema, pulmonary emphysema and pulmonary blebs are presented. Many of the patients were helped considerably, and some dramatically.

Penicillin blood levels were determined at intervals of thirty minutes, one hour and two hours after treatment, and one hundred and sixteen such determinations were charted. Peak levels were observed at the end of thirty minutes and in some cases persisted for as long as two hours. Generally,

the higher peak levels were observed with the higher doses and occasionally in the patients with suppurative processes, such as pneumonia and lung abscess.

Streptomycin aerosol was also employed in 2 cases of bronchiectasis due to Friedländer organisms, but streptomycin-resistant strains rapidly appeared and could not be eradicated despite tremendous doses. This phenomenon was not observed in the penicillin-aerosol-treated cases. Penicillin may be safely combined with streptomycin aerosol when indicated. Further studies employing streptomycin aerosol, perhaps combined with intramuscular therapy, may prove of value in the management of selected cases of laryngeal and pulmonary tuberculosis.

act that it seems incredible that the authors found only 430 cases recorded in the literature. To be sure, the vast majority of the cases have no apparent clinical significance. Seventy per cent occur in the upper gastrointestinal tract. The duodenum, stomach and jejunum are involved in that order of frequency. The rests, however, are found in diverticula of the stomach, duodenum and jejunum and in Meckel's diverticulum and also in the mesentery of the intestines, omentum, splenic capsule, gall bladder and bile ducts. Of the cases of clinical significance, 10 were in the stomach, 7 in the duodenum, 3 in the biliary tract and 2 in a Meckel's diverticulum. The largest, which was in the transverse mesocolon, measured 10.0 by 4.5 by 1.5 cm and was cystic, containing stones. Symptoms are similar to that of ulcer with bleeding. Cancer occasionally occurs. Hypoglycemia from aberrant pancreas is reported. Barbosa et al recommend removal of the rests when found and estimate that they will be observed once in each five hundred operations of the upper abdomen. It seems likely that this is a conservative estimate.

Acute pancreatitis occurring in previously cholecystectomized patients is discussed by Vuori,¹⁸ who encountered 4 such patients whose cholecystectomy had been performed from one and a half to four years previously. Cholecystectomy during the acute attack of pancreatitis was performed on 4 patients, 2 of whom developed further attacks of pancreatitis. Of 23 patients treated conservatively, 7 had recurrent disease. Vuori considers cholecystectomy to have no great prophylactic value in the prevention of pancreatitis. It seems reasonably well established, however, that gall bladders containing stones should be removed after patients have recovered from acute pancreatitis.

Adams and Nishijima¹⁹ present a new method of treating pancreatic cysts. In 2 cases the cysts were anastomosed to a jejunal loop with an enterointerostomy. In 2 others a pancreatic fistula was implanted in the jejunum. Five patients responded well to the usual method of marsupialization and drainage. Anastomosis of these cysts to the intestinal tract may be the method of choice, particularly if one is careful to shunt the main intestinal stream through a bypass.

Sailer and Zininger²⁰ report a case of a large islet-cell tumor without hypoglycemia in a forty-year-old woman with symptoms of duodenal ulcer. She was known to have had a mass in the epigastrium for two or three years. Exploration revealed a healed duodenal ulcer and a large nodular tumor involving the body and tail of the pancreas. Resection was done, and microscopic studies revealed an islet tumor of the delta-cell type, with local blood-vessel invasion. The patient received postoperative radiation but died of mesenteric thrombosis three years and ten months later. Autopsy revealed recurrence of the tumor in the remaining

pancreatic tissue, liver, mesentery, bladder and uterus.

David and Campbell²¹ bring the data concerning subtotal pancreatectomy for hypoglycemia up to date. They have collected the reports of 36 patients so treated, with 23 cases of recovery from hypoglycemia. Three of these were their own patients. Alloxan was ineffective in controlling the symptoms in all cases in which it was used. The authors believe that the reaction of human beings to this drug is different from that of experimental animals. It appears that the results justify subtotal pancreatectomy when a careful search fails to reveal an islet-cell tumor.

Whipple²² in his discussion of David and Campbell's paper, calls attention to the need for thorough mobilization of the duodenum to rule out tumor in the head of the pancreas. He had found the lesion in this location in 6 of 33 patients operated on. In 9 patients subjected to subtotal resection of the pancreas for hypoglycemia, the results were not good, and in 3 who were re-explored, the islet-cell tumor was found in the remaining head of the pancreas. Whipple further states that in some of the other 6 cases, he probably had not done a sufficiently radical subtotal resection. He remarks that total pancreatectomy is at times feasible and compatible with life.

An excellent review of radical surgery for lesions of the pancreas, as well as a detailed account of his personal experiences, is presented by Whipple²³. He has performed the operation on 8 patients in two stages and on 21 patients in one stage. Earlier experiences with the two-stage approach with the increased difficulties from vascular adhesions at the second stage led him to advocate the one-stage procedure. He states that adequate preoperative administration of vitamin K makes this practicable. Attention is called to the value of the observation and special handling of anomalous extensions of the uncinate process around the superior mesenteric vessels. Whipple refers to Brunschwig's²⁴ monograph on pancreatic tumors as an important contribution to the subject.

Waugh and Clagett²⁵ report the experience of the Mayo Clinic in radical operation for cancer of the ampulla of Vater and the head of the pancreas. Thirty patients have been operated upon, 20 by these authors. They prefer a one-stage approach but believe that operation on some poor-risk patients should be done in two stages. The follow-up results were disappointing in carcinoma of the pancreatic head but encouraging in lesions of the ampulla. The operative mortality was 20 per cent.

Dennis and Varco²⁶ in a collective review, found 104 cases of radical operation for carcinoma of the pancreas reported up to the time their paper was submitted for publication and added 13 new cases of their own. The total experience in the University of Minnesota hospitals at that time was with 46

tion of the pedicle as the primary step in the procedure, the spleen is freed from its loose diaphragmatic and peritoneal attachments by gentle manipulation. It is then possible to deliver the organ into the wound and accurately to secure its vascular attachments easily and under vision from in front as well as behind. This shortens the time of operation, reduces the amount of blood loss and prevents accidental injuries to the tail of the pancreas and the fundus of the stomach. Although this method has long been used by many surgeons, it is probably not so well known as it should be.

Rives⁹ added to knowledge in this field by describing a technic for simple delivery of the spleen when it was densely adherent from old inflammation. He suggested that by incision of the peritoneum above these attachments, the adherent peritoneum and the spleen could then be brought forward in the same manner used in the normally attached structure.

Babson and Morgan¹⁰ have added to the literature the reports of 2 cases of spontaneous rupture of an apparently normal spleen. There have been reports of at least 8 additional cases since 1937. It is difficult to be sure that many of these patients had not received trauma, with probable rupture of the spleen, some time previously. The delayed or secondary hemorrhage in such cases, occurring days or even weeks after the original and often ignored injury, is well known.

Best and Schmid¹¹ cite 3 cases of rupture of malarial spleens unassociated with trauma, treated with early diagnosis and splenectomy with recovery. They call attention to the possible increase of this complication of malaria in veterans who served in the Pacific zones. Mild exertion, coughing, sneezing and straining at stool are frequent causative factors. If the condition is unrecognized and the patient is not operated on, the mortality is 100 per cent, the average reported death rate in such cases is 50 per cent.

Waugh¹² has collected 15 cases of peritoneal autotransplants of splenic tissue following rupture of the spleen—9 by foreign and 6 by American writers. He reports in detail the case of a patient of his own who had been treated by splenectomy five years previously following an automobile accident. During laparotomy for hysterectomy, splenic implants the size of a pinhead to a pea were found scattered widely throughout the peritoneal cavity, particularly over the small bowel and cecum. Two of the implants were removed for microscopic confirmation.

Harmer and Chalmers¹³ have collected 163 reported cases of splenic cysts. Hydatid cysts were twice as frequent as those of any other type. They distinguish between true and false cysts: the former are dermoid, epidermoid, hemangiomatous, lymphangiomatous and serous cysts, and the latter are large and single and at one of the splenic poles,

with normal tissue elsewhere. They report in detail the case of a cyst in a twenty-four-year-old woman who had known she had a tumor mass for ten years. The specimen weighed 13 pounds and was 60 cm. in circumference.

Lazarus and Marks¹⁴ give an excellent discussion of primary malignant tumors of the spleen, with a review of the literature. These tumors, which are rare, are divided into two groups—primary non-vascular sarcomas, arising from the endothelium of the splenic sinuses, and malignant angiosarcomas. They are highly malignant and metastasize rapidly to the liver and less often to the lungs, the regional lymph nodes and the pancreas. The diagnosis may be suspected in a rapidly growing tumor that produces persistent pain, tenderness and cachexia. Early splenectomy is recommended.

Curtis and Movitz¹⁵ have established the importance of accessory spleens. In 174 consecutive cases of splenectomy and in 4 of abdominal exploration, they found one hundred and thirty-one accessory spleens in 56 patients, an incidence of 32 per cent. The number of accessory spleens varied from one to ten—26 patients had only one, and these were more frequent in the younger age group. The accessory spleens were located in the hilar region, the splenic pedicle, the retroperitoneal region near the tail of the pancreas, the great omentum, the colic ligamentary attachments, the mesentery of the small and large intestine and in the left adnexa in women. In all the multiple locations, there was always one spleen in the hilar region. This is explained on the basis of the embryologic development of the spleen. Curtis and Movitz point out the difference in true accessory spleens from a splenulus or splenosis often found in the abdominal cavity following ruptured spleens with hemorrhage. These authors attribute the failures, which generally occur following splenectomy for congenital hemolytic icterus and primary thrombocytopenic purpura, to the accessory spleens left in situ. They further warn against the danger of implants if the spleen is fragmented during its removal for these conditions.

Pugh¹⁶ has made an excellent collective review of splenectomy, with a historical background of interest. He discusses the indications, mortality rates and technic of operation. He adds 15 case reports of his own, with 1 fatal case due to other injuries and not related to the removal of the spleen.

THE PANCREAS

Pancreatic heterotopia is discussed by Barbosa et al.¹⁷ They review the literature and report 41 authenticated surgical cases, of which 25 were of clinical significance. The term "heterotopia" is applied to pancreatic tissue outside its usual or habitual location and without anatomic relation of continuity or of vascularization of the pancreas itself. These embryonic rests are seen so frequently during operations on the upper gastrointestinal

ound In the other 3 chronic infection and stones, the presence of arteriosclerosis, were apparently responsible for the bleeding. It is properly suggested that the gall bladder should be considered a possible source of obscure anemia of gastrointestinal origin. In 1931 White and Jankelson³⁶ reported similar cases and discussed the differential diagnosis in hemorrhage of gall-bladder origin. It is possible that this phenomenon may be based on the associated duodenitis secondary to inflammation of the gall bladder.

Norgore³⁷ collected from the literature 31 cases of traumatic rupture of the gall bladder, to which he added a case of his own in which the patient was a thirty-seven-year-old man who had been injured in an automobile accident. Attention was paid to a fractured left fibula until a few hours later, when the patient complained of abdominal pain. Seven days and a half hours after the accident, exploration revealed biliary peritonitis from a rent in the gall-bladder wall. The opening was closed, and cholecystostomy was performed, with uneventful recovery of the patient.

Extreme dilatation of the common hepatic ducts, with repeated operations for stones, sand and mud, are discussed by Sanders,³⁸ who has handled the problem in 22 cases by a generous lateral anastomosis between the enlarged duct and the duodenum, with satisfactory results. Usually, a wide dilation of the outlet of the duct, either by sharp incision or stretching, relieves this situation. Plastic operations from within the duodenum for this type of chronic dilatation with distal stenosis are described by Bailey.³⁹

Experience with benign stricture of the common bile duct at the Mayo Clinic is reported by Flickinger et al.⁴⁰ There were 188 patients, with a history of surgical trauma in 73 per cent. Symptoms were present immediately after cholecystectomy in 58 per cent, and there was a recognized accident during operation in only 9 per cent. Eighteen patients developed symptoms of hepatic-duct stricture three to twelve years after operation. It is significant that 12 per cent of all patients had been subjected to cholecystectomy in the absence of gallstones. All but 2 had had previous biliary-tract surgery. The usual procedure was choledochoduodenostomy or hepaticoduodenostomy. There was a 12 per cent operative mortality, 18 per cent of patients dying after leaving the hospital, 31 per cent continued to have symptoms. The 188 patients had had a total of two hundred and seventy-eight operations before admission to the clinic, and in these cases a total of two hundred and eighteen reconstructive procedures were done. Thirty patients who continued to have symptoms after re-establishment of continuity were finally well, 36 per cent of all survivors were well at the last report.

This distressing complication of biliary-tract surgery was discussed by Pearse,^{41,42} who made a collective review from correspondence with other

surgeons and from his own experience on the use of vitallium tubes in reconstructive operations for benign strictures of the bile ducts. Approximately 80 per cent of the patients had a satisfactory result at the time of his report. This is a high figure, and many of these patients will subsequently need further surgery to relieve the recurring symptoms. The discussion of the prophylactic measures concerning this problem is excellent. In only 1 patient out of 14 on whom the vitallium-tube method was used at the Massachusetts General Hospital was the final result apparently satisfactory. The duct in this patient had successfully been repaired over a vitallium tube used in the reconstruction two and a half years previously. When jaundice, pain, fever and chills brought the patient back to the hospital, the encrusted vitallium tube was acting as a large stone obstructing the outlet. Three other patients developed a new stricture — 2 above and 1 below the tube. The problem is serious, and repeated operations are often necessary before conditions are found that lend themselves to a suitable solution.

Peterson⁴³ has reported 42 cases of so-called "re-formed gall bladder," most of which resulted from a remnant of the gall bladder at the ampulla. Some apparently developed from a long cystic duct. Peterson considers the term a misnomer and believes that the condition actually represents the results of an incomplete operation. Symptoms are comparable to those in patients whose gall bladders have not been removed. In many cases the common bile duct is not dilated, as normally takes place following cholecystectomy, and symptoms are due to the intact nerve mechanism, which produces repeated spasm of the sphincter of Oddi. Peterson discusses the great care needed in cholecystectomy, with the absolute identification of all structures. It is pertinent to state that an incomplete operation under certain conditions of acute inflammation with edema about the ducts is preferable to the serious sequelae that often follow cholecystectomy.

Guyton⁴⁴ gives a case report of double gall bladder in a forty-two-year-old woman. Both bladders contained stones and were joined by a single cystic duct.

McLaughlin⁴⁵ operated on a twenty-five-year-old Negro who had suffered a weight loss of 25 pounds because of discomfort and a feeling of fullness after eating. A large tumor was palpated in the right upper quadrant, and a nonfunctioning gall bladder was reported after study. A large cyst of the choledochus was aspirated of 1000 cc of bile. This was dissected free from below upward, and all but a proximal remnant was removed. The remaining segment was anastomosed to the duodenum, with a good result.

Shallow et al.⁴⁶ collected from the literature 182 cases of congenital cystic dilatations of the common bile duct and reported 2 cases of their own. In the first patient, who was operated on in 1941,

cases of pancreatic cancer. Local excisions have been done in 9 cases, and radical operations in 14. In simple exploration the mortality was 23 per cent, and in radical extirpation, it was 29 per cent, whereas in local excision, it was 11 per cent. The authors consider most of the deaths to have been due to errors that are now avoidable. Like all surgeons experienced in this field, they prefer the one-stage operation, biliary-tract continuity from the common hepatic duct to the jejunum being established with implantation of the pancreatic duct. They believe that the gastrojejunostomy is best done about 40 cm distal to the implantation of these structures. This is a matter of choice, and most surgeons regard a much higher anastomosis between the stomach segment and the jejunum as satisfactory.

THE BILIARY SYSTEM

Clagett and Hawkins,²⁷ in an interesting case report, described the successful removal of the left lobe of the liver for multilocular cyst. A Bethune pneumonectomy tourniquet was used to control the base of the lobe during extirpation. Von Harbner is cited as having used a similar technic for the removal of a nonparasitic cyst in 1908. Such cysts in the liver are frequently associated with cystic disease of the kidneys. It is likely that many surgeons have had the opportunity to do this operation once or twice, but few reports have appeared in the literature.

Flynn²⁸ presents a timely discussion of the modern management of pyogenic liver abscess, with the successful treatment of 1 patient. He attributes his success to early diagnosis followed by adequate drainage and the use of penicillin. In the pre-chemotherapy era, the mortality for pyogenic liver abscess ranged from 50 to 95 per cent. In a recent case of an extremely large liver abscess of this type treated at the Massachusetts General Hospital, streptomycin was used following adequate drainage, with spectacularly quick sterilization of the abscess cavity.

Gatch, Battersby and Wakim²⁹ presented experimental evidence that cholecystitis is initiated by chemical action and that infection is due to the secondary invasion of bacteria on the chemically damaged gall-bladder wall. They produced acute inflammation in the gall bladders of dogs by introducing bile salts under pressure. Activated pancreatic juice caused acute edema and inflammation in the bile ducts of the animals when injected through the papilla of Vater. Stones in the gall bladder, with acute obstruction of the cystic duct, are believed to allow the imprisoned bile salts to damage the gall-bladder wall. Infection that follows depends on the degree of chemical action due to the duration of obstruction. Their deductions are as follows: early operation in acute cholecystitis is necessary only in fulminating cases, the gall bladder as a rule is not a focus of infection, prolonged

drainage is not necessary, there is little danger from spreading infection if the acute gall bladder is opened during operation, and exploration of the common hepatic duct is dangerous in the presence of acute edema and should be reserved for a later procedure if it becomes necessary.

Glenn and Heuer³⁰ present the results obtained in the New York Hospital in the treatment of acute cholecystitis over a thirteen-year period. They advocate early operation, which they have performed on 527 patients. Of 175 patients over fifty years of age, 9 succumbed, whereas only 4 of 352 under the age of fifty died. The over-all mortality was 2.5 per cent. Cholecystectomy was performed in 460 cases, being combined with choledochostomy in 43. Of the 67 patients treated by cholecystostomy alone, 5 succumbed. These results are in close accord with those at the Massachusetts General Hospital. The older the patient, the greater the risk, and in our series drainage of the gall bladder also carried a higher mortality rate than cholecystectomy.³¹

Johnstone and Ostendorph³² found 32 cases of perforation of the gall bladder in 12,000 consecutive cases at routine autopsy. One in every 375 persons in the group died of this complication. There were 22 men and 10 women in the series. General peritonitis was found in 42 per cent of cases, 47 per cent of the cases of perforation were undiagnosed before autopsy. The authors reported a series of 105 cases of acute gall-bladder disease treated surgically in which, as would be expected, the mortality was lower in patients operated on in the early days of the process.

Hicken and Coray³³ found spontaneous fistulas in some portion of the gastrointestinal tract in 42 per cent of their patients with biliary-tract disease. The fistulas were most frequently due to stone erosion, peptic ulcer and malignant disease ranking second and third as causes. Cholangiographic studies on the operating table are considered of great value in determining the extent and source of the fistula. Hicken and Coray advocate preventive measures by earlier treatment of gallstones and ulcer. Stage procedures are recommended, since the re-establishment of normal continuity of bile flow into the gastrointestinal tract leads to spontaneous closure of the fistula.

Goldman et al.³⁴ relieved 2 patients of residual common-duct stones with the introduction of Suby and Albright's solution G by means of Murphy drip through a T tube. They found, however, that this solution did not dissolve gallstones in a test tube. Since solution G is somewhat similar in composition to U.S.P. magnesium citrate solution, they concluded that the beneficial results were probably due to the relaxation of the muscle fibers of the papillary region by this drug.

Hudson and Johnson³⁵ report 4 cases of gastrointestinal hemorrhage from the gall bladder. In 1 a hemangioendothelial sarcoma of the gall bladder was

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

BENJAMIN CASTLEMAN, M.D., *Associate Editor*

EDITH E. PARRIS, *Assistant Editor*

CASE 33041

PRESENTATION OF CASE

A sixty-nine-year-old married farmer was admitted to the hospital because of a gradually developing stiffness and pain of the right knee.

The patient stated that in childhood he had received a severe laceration of the anteromedial aspect of the right knee causing immobilization for about two months. Seven years before entry he noted the gradual onset of pain and stiffness of the knee, as well as the appearance of a mass on the inner aspect. The stiffness and pain had grown worse, and the mass had gradually increased in size until two years before admission, when the increase had become more rapid. A cast was applied, baking, massage and manipulations of the neck and knee were without benefit. During the year before entry the pain became severe and constant and the mass grew larger, the patient continued to work, however.

Physical examination revealed a hard, fixed, tender mass on the posteromedial aspect of the right knee over the medial side of the joint and the condyle, extending posterolaterally in the popliteal space and proximally along the medial portion of the hamstring muscles. The mass was about the size and roughly the shape of two lemons, but with indefinite edges. The skin was freely movable over the tumor mass. The knee was in 120° flexion, with slight motion either active or passive. The leg was in adduction on the thigh. The right inguinal region was tender to deep palpation, but no large definite lymph nodes were felt.

The blood pressure was 184 systolic, 100 diastolic. The routine laboratory data were normal. An x-ray film revealed slight decalcification of the bones of the right knee joint, which was otherwise normal. Posterior to the joint there was a soft-tissue mass, measuring 6.5 by 5 cm., that contained flecks of calcification (Fig. 1). The blood serum calcium was 9.2 mg., and the phosphorus 2.4 mg. per 100 cc., the phosphatase was 5.6 Bodansky units.

An operation was performed on the thirteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. MERRILL C. SOSMAN* The x-ray films show a poorly defined mass that is best seen in the lateral view of the knee, on the film with the lighter exposure. The mass is made up of individual lobules, in some of which fine flecks of calcium are deposited. The mass extends beyond the upper end of the tibia and well up behind the femur, but there is no bone destruction. The joint looks quite normal in contour and width, and the mass is distinctly outlined in some sections, so that invasion of the soft tissues is not suggested. One of the first considerations with a mass anywhere in the body is to obtain a film of the chest. In the films in this case the lungs are clear of metastases. This looks discouragingly easy because the majority of firm nodular masses behind the knee, particularly if they contain small flecks of calcium, turn out to be synovial tumors. All of us, I am afraid, make the mistake of calling them "synoviomias." Do you call them "synoviomias" when you run across them?

DR. TRACY B. MALLORY We use that term because it is a standard one. I have never been altogether convinced that it was correct, however.

DR. SOSMAN Synovia, as I understand it, is the fluid in the knee joint. The synovial tissue, not the fluid, is the point of origin of the tumor, so that it is more accurately called "synovialoma." This was brought out by Jönsson† in an article based on 90 cases of malignant tumors of skeletal muscle, fascia, joint capsules and tendon sheaths, all of which had the same characteristics, irrespective of their point of origin. Histologically the tumors can be divided into the following eight groups: fibromyxosarcoma, endothelioma, spindle-cell sarcoma, hemangioblastoma malignum, angio-blastic sarcoma, what Jönsson called "polymorphous-cell sarcoma" (which is new to me but was so called, I suppose, because it had so many kinds of cells), alveolar sarcoma and round-cell sarcoma. These tumors, however, might be classified under a group of synovialomas of the malignant type.

Since the x-ray films suggest a synovialoma, I fear a trap, that diagnosis seems too simple. Of the other tumors that occur in this situation, a Baker cyst is one of the most frequent. Do you agree to that, Dr. Barr?

DR. JOSEPH S. BARR I think that it is the most frequent tumor in the popliteal space.

DR. SOSMAN The few I have seen were not so hard as this one was said to be, and none of them contained calcification. Have you seen calcification in a Baker cyst?

DR. BARR No.

DR. SOSMAN I therefore think that we can rule out a Baker cyst. The angiomas are usually softer.

excision of the dilated common duct was performed, with anastomosis of the two hepatic ducts separately into the duodenum. The second patient had an enormous abdominal tumor, from which 5800 cc of dark-brown material containing bile and amylase was aspirated, an anastomosis was made between the cyst and the duodenum. Both patients were well and symptom free at the time of the report.

(To be concluded)

DR MALLORY Dr Taylor, you saw this patient. Will you give your opinion?

DR. TAYLOR When I saw this patient on the Orthopedic Service, my reasoning was much the same as that of Dr Sosman. I examined the vessels at the ankle closely with the stethoscope. If Dr Van Gorder had not gone out so flat-footedly for synovialoma I should not have considered any other tumor with such enthusiasm.

DR SOSMAN Why did you think it was not synovialoma?

DR TAYLOR I thought that there was more calcification than there should be in a synovialoma.

DR SOSMAN In Jönsson's article some of the illustrations reveal calcification in the tumor.

DR TAYLOR They do, but not so much as that in his case.

DR SOSMAN I agree with you that there is generally little or no calcification.

DR TAYLOR Do you think that the long duration argues against that type of tumor?

DR SOSMAN I do not believe so. Synovialomas may have a low degree of malignancy. This tumor was of six years' duration, with a sudden exacerbation of growth. Synovialomas may begin as benign or slowly malignant tumors.

DR MALLORY I am forced to disagree. In our experience, synovialomas have been among the most malignant tumors.

DR SOSMAN In young people they are quite malignant but not in old people. If the tumor had been present for ten years and had been extremely malignant metastases would certainly have occurred by the time of admission.

DR TAYLOR I agree with Dr Mallory. I cannot imagine a malignant tumor that existed so long without dissemination, however.

DR SOSMAN Synovialomas are rare at this age.

DR MALLORY What does Dr Lingley think about it?

DR JAMES R. LINGLEY The x-ray appearance is consistent with that of synovialoma. But I agree that such a tumor is rare at the age of this patient. All the cases I have seen have occurred in young patients.

DR. SOSMAN I should have mentioned a chondrosarcoma, which almost always arises on an osteochondroma and in which the original bony pedicle is visible somewhere around the joint. I do not remember a case in which chondrosarcoma arose from the joint cartilage itself. It must be considered because cartilage is one of the main structures of the joint. Cartilage is an end product, a secondary type of cell differentiation, and a tumor might start from embryonic or fibroblastic tissue and develop into cartilage. I should like to add chondrosarcoma to the mesothelial group, which could all be called synovialomas.

DR MALLORY Will you tell us the operative findings, Dr Barr?

DR BARR I tried to steer a middle course between Dr Van Gorder and Dr Taylor in the diagnosis. I was not sure what the diagnosis was. I thought of all these things but did not commit myself beyond the fact that I considered this a tumor and not a Baker cyst. The exposure was made through a posterior incision. A hard mass was found about the size of a small orange or lemon, in exactly the situation where one would find a Baker cyst. It was somewhat lobular and irregular and of hard, rubbery consistence. It was excised and was found to communicate with the joint by a small pedicle. I had hoped that we could do an excision of the whole tumor, whatever it was, and therefore had not opened it for biopsy. The dissection planes opened freely and easily, exposing the whole tumor. When the joint at the base of the pedicle was opened, three small, free fragments of tumor came out of the joint. We noted at that time that we had not been successful in excising the tumor completely.

CLINICAL DIAGNOSIS

Malignant tumor of right knee

DR SOSMAN'S DIAGNOSIS

Synovialoma (mesoblastoma)

ANATOMICAL DIAGNOSIS

Chondroma of right knee

PATHOLOGICAL DISCUSSION

DR MALLORY The specimen that was resected had the characteristic gross appearance of a chondroma. It was hard but also elastic, white and glistening. Histologically it consisted of well differentiated cartilage with a good deal of intercellular matrix and comparatively few cells. The appearance was completely benign from the histologic point of view. How a chondroma could arise in this spot, where there is normally no cartilage, is an interesting speculation. It may have been secondary to metaplastic cartilage formation. Occasionally, inside the knee joint, extensive change of the synovial tissue into cartilage occurs. The three tiny fragments within the knee joint slightly suggested that possibility. On the other hand it is difficult to understand how a process of that sort could have produced a large tumor external to the joint cavity. It is true that this man had had a lacerating injury of the knee in childhood and may have had a slightly deficient posterior capsule. I called it a chondroma and assumed that it must have arisen from a metaplastic process — a new formation of cartilage in the joint capsule. Cartilage can form from fibrous tissue in innumerable parts of the body and sometimes forms visibly peculiar areas.

than the tumor in this case and usually contain phleboliths, particularly if they are venous angiomas. Lipomas usually show characteristic diminished density on x-ray examination when they are in or between the muscles and fascia, but they do not show the increased radiability if they are in the subcutaneous tissue, where they are surrounded by fat. Fibromas could conceivably originate from synovial tissue and therefore be regarded as synovial tumors.

DR GRANTLEY W. TAYLOR: The knee was listened to, nothing abnormal being heard, and there were perfectly normal pulsations in the ankle vessels. There was no bruit or pulsations over the mass.

DR SOSMAN: Arteriovenous aneurysms have either bruit or arterial pulsations or both in practically all cases.

I have not seen tuberculomas behind the knee, although they can occur anywhere. But the absence

FIGURE 1 *Roentgenogram of Right Knee.*

An aneurysm of the popliteal artery should be considered, and they contain calcium, particularly the arteriovenous aneurysm. These usually follow a penetrating wound, however, in which there has been an actual cutting of the artery and vein, resulting in arteriovenous communication, and produce channel-like structures. This case might possibly fit that description. In this situation that obsolete instrument, the stethoscope, might come into play. Was the stethoscope used on this knee?

of tuberculosis in the chest helps to rule out that diagnosis. Another possibility is a giant-cell tumor of the tendon sheath, which may occur anywhere but much more frequently around the wrist. It may be lobulated and may contain flecks of calcium.

In summary, I think that this was a mesoblastoma that arose not from endothelial or epithelial cells but from some of the mesoblastic structures. If I had not been invited to discuss this case I should have called it a synovialoma.

DR MALLORY Dr Taylor, you saw this patient. Will you give your opinion?

DR TAYLOR When I saw this patient on the orthopedic Service, my reasoning was much the same as that of Dr Sosman. I examined the vessels in the ankle closely with the stethoscope. If Dr Van Gorder had not gone out so flat-footedly for synovialoma I should not have considered any other tumor with such enthusiasm.

DR SOSMAN. Why did you think it was not synovialoma?

DR TAYLOR. I thought that there was more calcification than there should be in a synovialoma.

DR SOSMAN. In Jönsson's article some of the illustrations reveal calcification in the tumor.

DR TAYLOR. They do, but not so much as that in his case.

DR SOSMAN. I agree with you that there is generally little or no calcification.

DR TAYLOR. Do you think that the long duration argues against that type of tumor?

DR SOSMAN. I do not believe so. Synovialomas may have a low degree of malignancy. This tumor was of six years' duration, with a sudden exacerbation of growth. Synovialomas may begin as benign or slowly malignant tumors.

DR MALLORY. I am forced to disagree. In our experience, synovialomas have been among the most malignant tumors.

DR SOSMAN. In young people they are quite malignant but not in old people. If the tumor had been present for ten years and had been extremely malignant metastases would certainly have occurred by the time of admission.

DR TAYLOR. I agree with Dr Mallory. I cannot imagine a malignant tumor that existed so long without dissemination, however.

DR SOSMAN. Synovialomas are rare at this age.

DR MALLORY. What does Dr Lingley think about it?

DR JAMES R. LINGLEY. The x-ray appearance is consistent with that of synovialoma. But I agree that such a tumor is rare at the age of this patient. All the cases I have seen have occurred in young patients.

DR SOSMAN. I should have mentioned a chondrosarcoma, which almost always arises on an osteochondroma and in which the original bony pedicle is visible somewhere around the joint. I do not remember a case in which chondrosarcoma arose from the joint cartilage itself. It must be considered because cartilage is one of the main structures of the joint. Cartilage is an end product, a secondary type of cell differentiation, and a tumor might start from embryonic or fibroblastic tissue and develop into cartilage. I should like to add chondrosarcoma to the mesothelial group, which could all be called synovialomas.

DR MALLORY. Will you tell us the operative findings, Dr Barr?

DR BARR. I tried to steer a middle course between Dr Van Gorder and Dr Taylor in the diagnosis. I was not sure what the diagnosis was. I thought of all these things but did not commit myself beyond the fact that I considered this a tumor and not a Baker cyst. The exposure was made through a posterior incision. A hard mass was found about the size of a small orange or lemon, in exactly the situation where one would find a Baker cyst. It was somewhat lobular and irregular and of hard, rubbery consistence. It was excised and was found to communicate with the joint by a small pedicle. I had hoped that we could do an excision of the whole tumor, whatever it was, and therefore had not opened it for biopsy. The dissection planes opened freely and easily, exposing the whole tumor. When the joint at the base of the pedicle was opened, three small, free fragments of tumor came out of the joint. We noted at that time that we had not been successful in excising the tumor completely.

CLINICAL DIAGNOSIS

Malignant tumor of right knee

DR SOSMAN'S DIAGNOSIS

Synovialoma (mesoblastoma)

ANATOMICAL DIAGNOSIS

Chondroma of right knee

PATHOLOGICAL DISCUSSION

DR MALLORY. The specimen that was resected had the characteristic gross appearance of a chondroma. It was hard but also elastic, white and glistening. Histologically it consisted of well differentiated cartilage with a good deal of intercellular matrix and comparatively few cells. The appearance was completely benign from the histologic point of view. How a chondroma could arise in this spot, where there is normally no cartilage, is an interesting speculation. It may have been secondary to metaplastic cartilage formation. Occasionally, inside the knee joint, extensive change of the synovial tissue into cartilage occurs. The three tiny fragments within the knee joint slightly suggested that possibility. On the other hand it is difficult to understand how a process of that sort could have produced a large tumor external to the joint cavity. It is true that this man had had a lacerating injury of the knee in childhood and may have had a slightly deficient posterior capsule. I called it a chondroma and assumed that it must have arisen from a metaplastic process — a new formation of cartilage in the joint capsule. Cartilage can form from fibrous tissue in innumerable parts of the body and sometimes forms visibly peculiar areas.

DR SOSMAN There was no sign of invasion? Did the tumor shell out perfectly smoothly?

DR BARR Yes, just as smoothly as a Baker cyst

DR SOSMAN Was it attached to the cartilage of the knee joint?

DR BARR No, just to the capsule itself Was that true histologically?

DR MALLORY Yes

DR BARR Were the lines of excision beyond the tumor itself so far as you could determine?

DR MALLORY Yes

DR JOSEPH C AUB What is the function of the knee at present?

DR BARR It was markedly limited before the tumor was removed, the patient had practically no motion, obviously because the posterior tibial nerve lay directly over the tumor and on attempts at extension it was spread so that he could not extend the leg on account of the pain and could not flex it because of the tumor mass He has gained some motion but has still far from normal function of the knee

CASE 33042

PRESENTATION OF CASE

A sixty-six-year-old Greek textile worker entered the hospital because of anorexia and weight loss

Eighteen years before entry the patient had had a six-day episode of abdominal swelling Seven years later he had had a short period of illness associated with nausea Four years before admission an attack of sharp epigastric pain had occurred Two years later, following a tooth extraction, he developed chilly sensations and began to lose weight X-ray studies were said to have shown gallstones, and fourteen months before entry a cholecystectomy was performed at another hospital The gall bladder was chronically inflamed and thick walled, and contained several dark stones, the largest of which measured 1.2 cm in diameter The wound drained, and healing required five months, during which the patient developed jaundice and ran a slight fever Six months before entry he was readmitted to the hospital because of jaundice, pain in the chest and epigastric region, and vomiting for three days At that time examination of the blood showed a red-cell count of 3,440,000, with a hemoglobin of 62 per cent, and a white-cell count of 8500, with 77 per cent neutrophils The icteric index was 30 units The patient was placed on a low-fat, high-vitamin diet but continued to go downhill About once every week he had a shaking chill lasting two or three hours The urine became dark Four months before entry a laparotomy at the other hospital revealed a large liver Multiple punctures with a long needle failed to reveal an abscess The common duct was palpated, but no stones were found Postoperatively, the jaundice decreased slightly, but the

anorexia and weekly chills continued Frequent episodes of nausea and vomiting also began A month before entry the abdomen began to swell

The patient had had malaria when a youth He drank alcoholic beverages about once a week, but never to excess

Physical examination revealed a markedly jaundiced man, with evidence of recent weight loss There were soft axillary lymph nodes, measuring up to 1 cm in diameter A few crackling inspiratory rales were heard at the right base The heart was not enlarged The abdomen was distended, with a definite fluid wave The liver was moderately tender, and its edge was felt two fingerbreadths below the costal margin The prostate was smooth and of twice the normal size The right knee was ankylosed in full extension

The temperature was 99.4°F, the pulse 100, and the respirations 26 The blood pressure was 130 systolic, 64 diastolic

Examination of the blood revealed a red-cell count of 3,500,000, with a hemoglobin of 9.0 gm, and a white-cell count of 10,600, with 81 per cent neutrophils The serum phosphorus was 3.5 mg, the non-protein nitrogen 30 mg and the total protein 6.9 gm per 100 cc, with an albumin-globulin ratio of 0.6, the alkaline phosphatase was 27.5 Bodansky units per 100 cc The van den Bergh reaction was 4.3 mg per 100 cc direct and 5.7 mg total The prothrombin time was 23 seconds (normal, 19 seconds) The urine gave a +++ test for albumin and a +++ test for bile The stools were formed, tan and guaiac negative

X-ray films of the chest revealed a slightly elevated diaphragm on the right A plain film of the abdomen showed slightly dilated loops of small bowel with homogeneous, ground-glass density

A skin test with echinococcal antigen was negative

The patient received several blood transfusions, a high intake of glucose orally as well as intravenously and 24,000 units of penicillin every three hours At first there was a striking fall in temperature, but on the sixth hospital day, the temperature resumed a spiking course, frequently going above 102°F On the seventeenth hospital day a paracentesis was performed, and 3300 cc of yellow fluid with a specific gravity of 1.008 was withdrawn

Another gastrointestinal series showed rather extensive curling of the lower esophagus but no definite evidence of varices The duodenum and upper small intestine were within normal limits, but the patient was examined only in the horizontal position

On the nineteenth hospital day an operation was performed

DIFFERENTIAL DIAGNOSIS

DR ARTHUR W ALLEN Dr Schatzki, do you suppose that the x-ray films will help me?

DR RICHARD SCHATZKI I am afraid they will not of much help. The plain film of the abdomen at the time of admission shows slight dilatation of the small bowel and increased density of the whole abdomen, as one would expect with fluid in the abdomen. On the chest film in the lateral view, there is, in addition to what is stated in the report, slightly more lobulation than is seen in the average patient. Lobulation of the diaphragm does not necessarily mean anything so far as disease is concerned, but in a patient with liver disease I should make a mental note of it but should usually not record it. Perhaps I am leading you astray. I do not know the answer.

DR ALLEN Neither do I.

DR SCHATZKI These films show a small hiatus hernia and a slightly tortuous esophagus, as one would expect with a high diaphragm. There is some curving of the esophagus, and the folds look thicker than they should be, even considering the high position of the diaphragm. In a patient with a tortuous esophagus, the differentiation of folds and varices is rather difficult and sometimes impossible to make, unless the varices are definite. They are certainly not definite in these films.

DR ALLEN We have a clear-cut story that ought to be correct so far as the findings at operation are concerned, in spite of the fact that this man was probably born in Greece, where echinococcal disease is frequent. He was undoubtedly studied with that point in view, and it is possible that the second exploration in the other hospital was performed to demonstrate an echinococcal cyst.

A disturbing feature about the history from the standpoint of diagnosis is the finding in the peritoneal cavity of a large amount of yellow-stained fluid with a low specific gravity. One must assume that this fluid was not bile but was possibly slightly bile stained, as all the tissue fluids were, and that it did represent a true ascites. That is unusual in the type of situation that I believe existed in this case. Free fluid is often found in patients who are chronically ill, particularly if they are ill with a disease that affects the liver. The negative x-ray examination for esophageal varices and the fact that there was no blood in the stools are evidence that this was not a simple cirrhosis of the liver of an independent nature. Of course, this patient had cirrhosis, which was probably a biliary cirrhosis on the basis of obstruction in the bile duct. I cannot see any connection between the early history of malaria and the condition as it is presented in the record.

The history goes back eighteen years, with a short episode of abdominal distress and swelling, lasting six days, that could have been the initial onset of difficulty with gallstones. There was another

episode of nausea eleven years before entry, and an attack of sharp epigastric pain, which is compatible with real biliary colic, seven years later. The difficulty starting two years before entry, following the tooth extraction, represented the acute phase of the process—the tooth extraction, in my opinion, had nothing to do with the weight loss and the chills and fever, which indicate a cholangitis on the basis of infection, primarily originating in the gall bladder itself and finally involving the bile ducts. It would be extremely difficult to visualize this picture on the basis of any nonsurgical disease. The only point that bothers me is the ascites. The chance that this illness was caused by a tumor in the region of the head of the pancreas or the papilla of Vater is not great, although such a tumor, of course, would account for the ascites better than the situation that I believe existed.

The fact that the stools were tan interests me a little. No chemical test for bile is recorded. A deeply jaundiced person could have a stool that might be called tan because all the fluids in the body are naturally bile stained, but I believe that we must accept the fact that some bile was getting into the gastrointestinal tract, although not much, as in many patients with cholangitis with complete or almost complete obstruction. A small amount of bile seeps through an opening so small that on the operating table one cannot actually visualize it and wonders how any bile can get through at all.

At the first operation, when the gall bladder was removed, stones were found in a chronically thickened gall bladder. The important feature to me is that drainage through the wound continued for five months after the cholecystectomy. We are not told the nature of the fluid drained, but we must assume that it was bile. As this drainage to the outside began to decrease, the patient became jaundiced and began to have chills once a week. So long as bile was draining to the outside these chills probably did not take place, and he might have been in a fairly reasonable state of health, although the anorexia and weight loss were probably not corrected because we have no information that the lost bile was returned in any way to the gastrointestinal tract.

The causes of jaundice with cholangitis following cholecystectomy may be two: the first is an overlooked obstruction in the common bile duct, which may allow a certain amount of bile to get into the intestinal tract and which may occur with no evidence of jaundice. When there are a number of stones, bile seeps around them as water does in a stone drain in a wet field, and jaundice does not occur. A single stone or stones headed by a large stone in the ampulla are likely to cause complete jaundice and to allow less bile to seep through.

Cases of tumor in the region of the head of the pancreas often have intermittent phases of jaundice, and a certain amount of bile frequently gets into the gastrointestinal tract in spite of obstruction. The other cause (and I am sure that I was assigned this case because it was hoped that I should arrive at this conclusion, which is probably wrong) is that at the time of the cholecystectomy an injury to the common duct occurred. Unfortunately, this takes place often enough so that in a clinic such as this there are usually one or two such patients who have been sent in to have something done about the situation. This patient must have had an obstruction of some sort or an injury to the duct for bile to drain for five months after cholecystectomy. The gradual onset of the final condition following the original operation makes one wonder whether a tenting of the common bile duct, with a ligature around it, finally produced complete or nearly complete obstruction of the duct. The type of injury that usually precipitates early recognition is one in which the common bile duct is mistaken for the cystic duct and a large portion of it is removed.

I therefore conclude that this man had an injury to the common bile duct, and that he had, of course, biliary cirrhosis due to the obstruction and cholangitis in addition to or as a result of the injured duct.

DR TRACY B. MALLORY: Will you tell us the opinion on the wards, Dr. Volwiler?

DR WADE VOLWILER: There were three things we argued about considerably on the medical service before exploration. The most troublesome was the problem of ascites, which also bothered Dr. Allen. It was certainly a transudate. We did not believe that a biliary cirrhosis was necessarily present. The albumin-globulin ratio, although considerably reversed, was not lower than that in prolonged obstructive jaundice and malnutrition without biliary cirrhosis. We have seen several cases in the last few years in which an inflammatory process in the region of the gall bladder or a pyelophlebitis has occurred with massive ascites. Dr. Linton's theory was that a partial lymphatic block allowed localization of fluid in that area. We have seen several patients with complete biliary obstruction, with clay-colored stools of four to six months' duration, who at operation or at post-mortem examination showed no histologic signs of biliary cirrhosis. I think that there is no way of predicting whether or not such cirrhosis will be found, unless there are secondary xanthomas. I am sure that the element of infection is important in its production, and I suppose that in this case it would be a safe bet.

We were also uncertain whether or not there were hepatic abscesses, with the high temperature and the chills and fever. The liver was definitely tender to palpation, which we thought was another point in favor of abscess, although the white-cell count was always much lower than that in most cases.

DR MALLORY: Did you assume that the liver was large?

DR VOLWILER: We thought it was somewhat larger than normal, but we see enlarged livers merely from bile stasis, without any additional intrahepatic fibrosis.

DR ALLEN: I might add that I have seen a number of these patients with injuries to the bile duct who finally came in with a tender liver, not all are tender, but some definitely are.

CLINICAL DIAGNOSIS

Common-duct stone

DR ALLEN'S DIAGNOSES

Common-duct injury
Biliary cirrhosis
Cholangitis

ANATOMICAL DIAGNOSES

Defect of common bile duct, postoperative
Cholangitis
Biliary cirrhosis
Erosion of intrahepatic branch of portal vein, with hemorrhage
Intrahepatic cholelithiasis
Bronchopneumonia
Recent operative wounds, choledochojejunostomy, jejunojejunostomy

PATHOLOGICAL DISCUSSION

DR MALLORY: At operation only insignificant remnants of the common bile duct could be found. It was necessary to do an anastomosis of a loop of jejunum to the right hepatic duct practically within the hilus of the liver. This was carried out successfully, although with considerable difficulty, and a series of adjusting anastomoses were made in the small intestine. A drain to the exterior was also placed in the hepatic duct. Following operation the patient did well for about two weeks and then began to have a series of massive hemorrhages through the drainage tube in the abdominal wall and also in the bowel. He passed several tarry stools. On two occasions he bled himself out almost completely, passing at one time into a stage of unconsciousness. He was revived with multiple transfusions. Two days after one of these episodes he was up in a wheel chair again and, for the moment, in excellent condition. He had a final massive hemorrhage, however, and died.

At autopsy we found that a large segment of common bile duct was missing. Only 2 or 3 cm. of the duct remained next to the duodenum, and a large stone, nearly 2 cm. in diameter, was found impacted in the ampulla. Above the point where the duct had

transsected additional stones were found in
nches of the hepatic duct throughout the left
e of the liver. The intrahepatic bile ducts were
markedly dilated in both lobes, there were multiple
stones in the ducts of the left lobe, but none in the
ducts of the right lobe. There was an extremely
severe biliary cirrhosis — one of the most marked
that I have ever seen. There was also a marked
cholangitis extending throughout all the radicles
of the biliary system. It was an inflammatory
process extending from the infected bile ducts that
had eroded into a branch of the portal vein within
the liver and had produced the fatal hemorrhage.
One of the surprising facts at autopsy was that,

in spite of the long-continued obstructing jaundice
and the multiple episodes of hemorrhage into the
ducts, the kidneys were almost perfectly normal.
There was terminally a rather extensive broncho-
pneumonia.

DR ALLEN: Was there any evidence that the ero-
sion between the hepatic duct and the branch of the
portal vein had been produced by the tube used at
the anastomosis?

DR MALLORY: As I read the record, I do not be-
lieve so.

DR ALLEN: I do not believe that we have ever
seen such erosion in all the cases in which we have
repaired the bile duct.

CONTROL OF TYPHOID FEVER AND TUBERCULOSIS

THE effectiveness of the application of sound public-health principles is no better illustrated than by the decrease in deaths from typhoid fever that has occurred in the large cities of the United States during the last thirty-six years. In 1945, according to the most recent report,¹ there were only 80 deaths in seventy-eight cities with a total population of 35,895,638, whereas in 1910 there were 4637 deaths in the same cities, whose total population at that time was 22,573,435. The respective death rates per 100,000 are 0.22 and 20.51, a difference of nearly a hundredfold. In 1945, fifty-six cities reported no deaths, thirty-one had death rates varying between 0.1 and 0.9, five between 1.0 and 1.9, and one between 2.0 and 4.9, whereas in 1910, of the seventy-

seven cities whose statistics are available, two had rates ranging from 5.0 to 9.9, and in the remainder the rates were 10.0 and over. In the period 1941-1945, the rates according to geographical divisions are as follows: 0.14, New England; 0.16, East North Central and West North Central; 0.17, Middle Atlantic; 0.23, Mountain and Pacific; 0.54, South Atlantic; 0.57, East South Central; and 0.89, West South Central.

Owing to proper control of water supplies and sewage disposal and to regulations governing the distribution of milk and other foodstuffs, including the handling of food, epidemics of typhoid fever are essentially things of the past. The cases that do occur, particularly those in areas with low mortality rates, are usually due to direct or indirect contact with an unrecognized typhoid carrier. In Massachusetts, for example, there are approximately 170 recognized typhoid carriers at the present time, and it is estimated that there are probably in the neighborhood of 1000 unrecognized carriers. Although it is possible to minimize the risk of contagion from those who are known to excrete typhoid bacilli from the gastrointestinal or urinary tract, obviously nothing can be done to control the spread of infection by the unrecognized carrier. Over the course of years, however, the number of such persons is certain to approach zero. In spite of the fact that the subcutaneous injection of typhoid vaccine results in a reasonably effective immunity against typhoid infection, there appears to be no indication for its use, unless a person resides in or plans to visit an area in which the disease is endemic or temporarily epidemic.

This present mode of infection in typhoid fever parallels that for tuberculosis, in that both are largely contracted from persons with unrecognized infections. Now that tuberculosis has been practically eliminated from dairy herds and the milk from the occasional tuberculous cow is rendered innocuous by pasteurization, the spread of this disease depends chiefly on contact with human tubercle bacilli from persons having recognized or unrecognized open tuberculous lesions.

Fifty years ago, when infection with tuberculosis was almost universal, little could be accomplished in limiting the foci of infection. With a drop of some

er cent in the death rate, however, the picture radically changed and, as in typhoid fever, the serious case has become the primary object of attack. In tuberculosis only the open case is a source of infection, and the continued, steady decline of disease in this country during the last seventy-years is convincing evidence that, on the whole,

the case is giving rise to less than one new case. Frost² has well pointed out, this can only mean that the biologic balance is against the survival of tubercle bacillus and, if this balance can be maintained, that the ultimate eradication of tuberculosis is a possibility.

As the incidence of tuberculosis decreases, concentration on the open case will yield increasing returns. This means early diagnosis and prompt hospitalization of active cases and routine x-ray examination of all family contacts, especially adults. Our experience has shown, however, that, even under the most favorable conditions, not over half the new cases can be traced to direct contact, the rest must be spread wide to be really effective. This has become practical with the development of photofluorography during the past few years. Under the selective Service system nearly 20,000,000 young men and women in this country were screened with x-ray films of the chest and approximately 1.25 per cent were rejected because of the findings. On the basis of discharge examinations it is estimated that the incidence of tuberculosis in the armed forces of the United States in World War II was only about one-tenth of that in World War I. At the same time the 2,000,000 workers in arsenals, shipyards and other industries received routine x-ray examination, largely through the efforts of the United States Public Health Service.

Facilities for routine x-ray examination of household contacts of tuberculous patients are now available to physicians in nearly all states. Many state health departments, often with the assistance of voluntary associations, have embarked on programs for the routine examination of industrial workers. Some have already begun mass x-ray examination of the adult population of entire communities for the discovery of unrecognized foci of infection. Hospitals offer a fertile field for this type of case finding, both for the detection of unsuspected cases

among patients and for the protection of nurses and other employees.

The problem of control in tuberculosis is more complex than that of typhoid fever, but the principles are becoming more and more similar. In tuberculosis, individual resistance plays an important but still largely unmeasured role and the influence of environment was again tragically demonstrated in invaded countries in the recent war. When, in addition to routine examination of suspects and household contacts, mass x-ray screening of the adult population is provided, as well as adequate sanatorium facilities for the isolation and treatment of all active cases, and when nations have learned how to live for more than one generation without war, tuberculosis should become as truly preventable as typhoid fever.

FULTON'S HARVEY CUSHING

MEDICINE in general has been unusually fortunate in the biographers of her worthies. *The Life of Sir William Osler*, by Harvey Cushing, a full two-volume estimate of Osler and his influence on Canadian, American and English medicine, published in 1925, set a standard never before reached in medical biography in this country and indeed seldom equaled in all the history of physics. One can only compare it with Stephen Paget's discriminating study of Victor Horsley or with Humphry Rolleston's thoughtful biography of Clifford Allbutt, to mention only two outstanding modern examples. As the Cushing volume is so richly autobiographical, there comes to mind also those more personal reminiscences of contemporary physicians, such as Hans Zinsser's appealing *As I Remember Him*. *The biography of R. S. Ramón y Cajal's penetrating Recollections of My Life*, Bland-Sutton's sprightly *The Story of a Surgeon*, August Forel's *Out of My Life and Work* and, in a lighter vein, *The Horse and Buggy Doctor* by Hertzler and *Sands of Time* by Purves-Stewart. To these of recent date should be added the fine tribute to Théodore Tronchin by Henry Tronchin and the memorable account of

William Henry Welch by Simon Flexner and his gifted son James Thomas Flexner

To this brief list, fully recognized as incomplete, must now be added the biography of Harvey Cushing by John F. Fulton. Few biographies are more satisfying than this competent life. Much was told by Cushing himself, and a mosaic, based on such original sources, has been judiciously fitted into a full portrait by his skilful biographer.

A review of the book appears elsewhere in this issue of the *Journal*. The volume is a worthy contribution to medical biography, and physicians, medical students and indeed the lay public should find inspiration and a stimulus to greater things in reading the life of the outstanding surgeon of his age and a medical pioneer of no mean ability.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

PAINTER — Charles F. Painter, M.D., of Brookline, died January 6. He was in his seventy-eighth year.

Dr. Painter received his degree from Harvard Medical School in 1895. He was formerly dean of Tufts College Medical School, librarian of the Boston Medical Library, for many years a member of the editorial board of the *Journal of Bone and Joint Surgery* and editor of the *Yearbook of Orthopaedic Surgery*. He was a fellow of the American College of Surgeons, an eminent member and former president of the American Orthopaedic Association and an emeritus member of the American Academy of Orthopaedic Surgeons.

His widow, a son and a daughter survive.

STONE — George H. Stone, M.D., formerly of Worcester, died January 4. He was in his sixty-sixth year.

Dr. Stone received his degree from Bowdoin Medical School in 1908. He was formerly superintendent of Worcester Memorial Hospital and was a fellow of the American Medical Association.

NEW HAMPSHIRE MEDICAL SOCIETY

ROCKINGHAM COUNTY NEWS

A leaflet *Rockingham County Medical Society News* is now being sent out monthly from the office of the secretary, Dr. Donald W. Leonard, of Exeter. The December, 1946, copy contains a short report of the annual meeting, an account of a meeting of the Women's Auxiliary, information from the secretary of the New Hampshire Medical Society, a list of the officers of the county society and a note regarding the annual meeting of the New Hampshire Medical Society.

By this means, the officers of the Rockingham County Medical Society plan to keep its members informed concerning news within the county and to carry announcements, with the hope that this will stimulate greater interest in the affairs of the society, particularly its regular meetings.

NOTE

The following New Hampshire physicians were recently appointed fellows in the American College of Surgeons: William P. Clough, Jr., New London, Edward D. Hagerty, Nashua, B. Read Lewin, Claremont, and Raymond R. Perreault, Rochester.

BOOK REVIEW

Harvey Cushing: A Biography By John F. Fulton, M.D. 754 pp. Springfield, Illinois: Charles C. Thomas, 1946. \$5.00.

Harvey Cushing, neurosurgeon, author, diarist, bibliophile and scholar, whose name ranks with those of William Osler, William H. Welch and others, stands out as one of the great physicians of our time. He was quite possibly the most distinguished graduate of the Harvard Medical School, certainly one of the greatest of American surgeons and, without question, a man whose influences in more than one field of medicine will have enduring recognition. To have virtually developed a new department of surgery, to have written the foremost biography of a contemporary medical figure, — a book widely proclaimed both in and out of his profession, — and to have greatly enriched the fields of medical history and science are accomplishments of no mean order. Harvey Cushing did each of these and, in addition, molded the lives of countless young men who later, in turn, have made no inconsiderable advancements in the progress of medicine. Not the least of those he trained is his talented pupil and friend of his later years, a distinguished professor of physiology and the author of his biography. Harvey Cushing, long anticipating that an account of his eventful life might be of use to future students of medicine, kept voluminous notes and diaries, almost writing his own biography by the daily activity of his pen. Few men have left a larger accumulation of pertinent material for a competent biographer to sift, or more remarkable papers and drawings on which the latter could base the reactions of his subject to the events of his time.

Harvey Cushing was born in Cleveland, Ohio, on April 8, 1869, the descendant of an English family that came to New England in 1638. His grandfather, Erastus Cushing, M.D., the son of a country doctor, emigrated by the Erie Canal to the Western Reserve of Connecticut in 1835, and there, in Cleveland, his father, Henry Kirke Cushing, M.D., was brought up. The latter was a shy, somewhat austere and puritanical person, although highly regarded as a practitioner of gynecology and obstetrics. With the heavy responsibilities of a large family, Dr. Cushing was frugal to the point of penuriousness. Often silent and secretive for days, speaking to no one in his family, he led at times a somewhat somber life. Harvey Cushing's mother, on the other hand, was even-tempered, forceful and kindly, with humor, grace and an inner gaiety of spirit. Some of these qualities, as well as some from his father, Harvey Cushing inherited in full measure. He was the youngest in a family of ten children, only seven lived to maturity. One brother also became a physician, and the others were supplied by their thrifty father with splendid educations. The eldest graduated from the Harvard Law School and practiced his profession in Cleveland for many years, another graduated from Cornell University and became a geologist of note, the older brother who became a physician went to Cornell and then to the Harvard Medical School, and Harvey was sent to Yale and then to the Harvard Medical School. Surely few fathers have given their sons better educational opportunities than did the penurious Cleveland practitioner.

Harvey Cushing's career at Yale was that of an undistinguished but creditable scholar, a superb athlete, particularly brilliant in baseball and adept at gymnastics, and a popular boy who was elected to the proper clubs in spite of his father's disapproval of both intercollegiate athletics and college societies. Cushing's ability to make sketches and his powers of description were already discernible in his college years. Preserved are the diagrams of his first quarters in New Haven and a striking description, in a letter to his mother, of the blizzard of 1888.

Turning to medicine, Cushing entered the Harvard Medical School in 1891. The high stone steps of the building (now part of Boston University) on Boylston Street in Boston tempted him to repeat his performance off the steps of the Yale gymnasium, and with a lighted cigarette in his mouth he turned a back somersault, landing upright on the bare sidewalk with the cigarette still going. This no doubt made the transition from New Haven to Boston less difficult than he had expected, but Cushing soon developed an uneasiness about Harvard that he never quite overcame. He soon became heavily involved in his studies, however, and by the second half of his second year he was etherizing for Dr. Warren. One

his first patients died under the anesthetic, a profound shock to the sensitive young medical student. Later, he became depressed with frustrations and a feeling of inadequacy, these he overcame by dint of hard work, which won for him a surgical internship at the Massachusetts General Hospital. He was regarded by his friends as the ablest man in his class. While a student he, with Amory Codman, devised a method for recording the temperature and pulse of a patient during etherization. When serving as an intern, he and Codman again collaborated, this time on x-ray photographs. In the spring of 1896 they purchased a crude machine and took pictures, activating their x-ray tube by a hand-driven electric machine and using exposures up to twenty minutes to get a clear plate. Cushing, even in those days, was a perfectionist, difficult to work with and ambitious almost to a point of intolerance, arousing many animosities among his fellow workers. He was also critical of his surgical teachers, writing at "these men operate about the way a commercial traveler takes breakfast at a lunch counter."

In 1896 Cushing went to the Johns Hopkins Hospital to serve as an assistant resident in surgery under Dr. William Halsted. There he remained for thirteen years. Bringing with him his x-ray apparatus from Boston, in 1896 Cushing made the first x-ray films taken at Hopkins. A patient with a bullet in the cervical spinal cord interested him and, using photographs of x-ray films as illustrations, he published his first original piece of writing in 1897. Cushing soon became a great favorite with the patients in the wards—but not always with the nurses or his fellow members of the staff. Dr. Halsted was often sick, and Cushing saw little of him during his three years as resident. He thus had more responsibility than most young surgeons and more opportunity for developing his own technique. Following Halsted's work on cocaine infiltration, Cushing began a series of studies on block anesthesia in 1898. When came a pioneer development in the handling of patients with typhoid perforations and a paper on gonococcal peritonitis.

Going abroad in 1900, Cushing went to Berne, where he did experimental work in Kronecker's laboratory and attended Theodor Kocher's clinic. He carried his experiences with animals in Kocher's laboratory, where he observed the brain through a small window in the skull to Mosso in Turin. There, using the same technic, he studied a man with a cranial defect. Seeing a model of Riva-Rocci's blood-pressure device in Pavia, Cushing promptly sketched it and brought a model back to Baltimore when he returned home. Most of his investigations at various centers were followed by papers, published in current journals. In some instances these had a bluntness and lack of diplomacy that caused considerable disconcertion among his senior men, who were accustomed to write papers in their own names that were based on the work of their pupils. Later came a productive month with Sherrington in Liverpool before returning to America.

Returning to Johns Hopkins Hospital in 1901, at the age of thirty-two, Cushing began practice, living next door to the Oslers, at 3 West Franklin Street. With Thomas B. Fitcher and Henry Barton Jacobs, he became one of the "latch-keyers" to the "man-next-door," William Osler, whose life he described many years later in the most successful medical biography of its time. He then developed a growing interest in surgery of the nervous system, spaced with experimental studies on blood pressure, courses in graduate instruction in general surgery and studies in the physiology of saline solution.

Cushing had long shown more than a casual interest in neurologic surgery, first at the Massachusetts General Hospital and later in his experimental researches abroad. At Hopkins his attention was directed to this special field of therapy through a simple operation for meralgia paresthetica on the astrophysicist Simon Newcomb, a long series of investigations on the Gasserian ganglion and a special assignment to this department of surgery under Dr. Halsted. By 1904 he was ready to make his first report as a "brain surgeon," and in 1908 he wrote the long chapter "Surgery of the Head" for Keen's *Surgery*. The operative mortality was so high in those days that Cushing at once turned to the problem of improvement in technic, devising the cranial tourniquet and new instruments. Also, he began his study of the pathology of brain tumors, noting their variation in recurrence and other features of their natural history.

From 1908 to 1912 came the period of the experimental work on the pituitary body, the development of suboccipital exposure for cerebellar tumors, trips to Europe, the first

operation on General Leonard Wood in 1910 and the publication of the pituitary monograph in 1912. Cushing had a curious way of setting up a theory and then making every effort to prove it, even when accumulated evidence showed that his theory was based on unsound premises. He was led astray regarding the finding of pituitary extract in the spinal fluid and never admitted that he was wrong, a curious foible in a man who had so many obvious virtues as an investigator. This caused some of his junior associates to waste valuable time in attempting to establish Cushing's original contention. The pituitary monograph, however, was characterized by the remarkable case histories, the discussion on acromegaly, gigantism and hypopituitarism, the microscopic studies and the development of the surgical approach to pituitary tumors—all contributions of major importance. As Osler remarked, it opened "several new chapters in cerebral physiology, to say nothing of metabolism."

In 1912 Cushing removed to the newly established Peter Bent Brigham Hospital in Boston as surgeon-in-chief and at the same time became the Moseley Professor of Surgery at Harvard University. Here he continued and greatly expanded his brain-tumor clinic, developed a new series of research problems, trained a long list of young students, interns and residents and made Boston a center for neurosurgery. His special field of endeavor was twice interrupted by war—first in 1915 when he led the Harvard Surgical Unit to Paris and secondly by his command of Base Hospital No. 5, which went overseas in 1917. His voluminous diaries were partly published in the book "From a Surgeon's Journal" in 1936. Back in Boston, his clinic ever expanding and the Society of Neurological Surgeons founded, Cushing turned to preparation of the Osler biography, his major literary work and possibly his greatest contribution to fame. The book, published in 1925, received wide acclaim and was awarded the Pulitzer Prize in 1926. Five more years brought his operations on brain tumor cases to over two thousand, and with the description of a new syndrome, pituitary basophilism, his active work in surgery drew to a close. His last operation occurred in August, 1932, at the age of sixty-three. Leaving Boston he settled happily in New Haven near his old and cherished Yale University, where he remained, developing a brain-tumor registry, exploring his library and making plans to leave it to the University, writing his bibliobibliography of Vesalius and, except for periods of great pain and distress, enjoying life to the utmost with old and new friends until his death in 1939.

His biographer has wisely kept a restraining hand on the more turbulent moments, and with studied care he has etched a portrait of Cushing without giving offense. Harvey Cushing was too great a man for some of his nimble jumps into controversy not to be overlooked, as he did so frequently himself. But, as with his famous backward somersault, he usually came up aright, with cigarette glowing and much justified applause for his audacity. In the intenseness of his life much was sometimes ruthlessly pushed aside, but he not infrequently showed the warmer side of his nature with equal or even greater fervor. So many acts of kindness went untold—medical students helped both financially and spiritually, friends made unexpectedly happy by unannounced visits, gifts on appropriate occasions and messages to those in distress. Few men have had a "harder" practice, for patients with brain tumors bring many problems to the neurosurgeon, often of a tragic nature. Cushing felt deeply and was profoundly touched by misfortune, as many a patient and friend can testify. His brusqueness, too, hid an essentially shy, sensitive nature, for at heart he was a deeply lovable person, driving himself and being driven by the environment he created to heights not often attained. He flew high and straight, maintaining an altitude of greatness throughout his life. In reading his skillfully written biography one never glimpses Cushing as "grounded."

The book is published in a fitting manner, finely printed and illustrated. Only two devoted friends, his biographer and the publisher, could combine to make a volume so representative of the man who meant so much to both of them. Modestly priced to fit the pocket of the medical student of the day, the book should be compulsory reading for every man and woman entering medicine as a profession. Poor indeed is the student who cannot gain from reading the life of one of America's finest products, a man who inspired his contemporaries as few others have done and who will continue to enrich the lives of those that come after him, thanks to this worthy volume.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

The Clinical Application of the Rorschach Test By Ruth Bochner, M.A., psychologist, Bellevue Psychiatric Hospital, New York City, and Florence Halpern, M.A., psychologist, Bellevue Psychiatric Hospital. Second edition, revised and enlarged. 8°, cloth, 331 pp. New York: Grune and Stratton, 1945. \$4.00.

The first edition of this book was well received when published a few years ago. Since that time the authors have added a considerable amount of material on this subject, one of the most frequently used tests in studying the field of personality. The authors believe that this test contributes materially to the subject in a manner that cannot be obtained through the medium of other techniques. The test, however, as they point out, has distinct limits. The book has become a standard text in its field.

Active Psychotherapy By Alexander Herzberg, M.D., Ph.D. 8°, cloth, 152 pp. New York: Grune and Stratton, 1945. \$3.50.

The author has a wide experience in the treatment of psychoneuroses, both in Germany and in England, and this book reflects his experience. Many case histories are given in some detail, along with facts on the technique of psychoanalysis and its value to psychiatry. The book is concise and practical, for it is based on the study of 500 cases over a period of twenty years.

The Osseous System. A handbook of roentgen diagnosis By Vincent W. Archer, M.D., professor of roentgenology, University of Virginia Department of Medicine. 8°, cloth, 320 pp., with 148 plates. Chicago: The Year Book Publishers, Incorporated. \$5.50.

This book has been written for the occasional radiographer and should therefore be considered a primer rather than a comprehensive text. In writing the work the author has taken advantage of mistakes that have been observed over a period of twenty years in a teaching position and in hospitals, as well as those made by individual physicians.

Skin Diseases in Children By George M. MacKee, M.D., professor of clinical dermatology and syphilology, New York Post-Graduate Medical School, Columbia University, and Anthony C. Cipollaro, M.D., associate in dermatology and syphilology, New York Post-Graduate Medical School, Columbia University. 8°, cloth, 448 pp., with 225 illustrations. New York: Paul B. Hoeber, Incorporated, 1946. \$7.50.

This book has been written chiefly for the general practitioner, and the second edition has been thoroughly revised to date. Special attention is given to methods of treatment that are suitable for the use of the family physician. Many new photographs and colored plates have been added.

Gastro-Enterology. Volume III. The Liver, Biliary Tract and Pancreas, and Secondary Gastro-Intestinal Disorders By Henry L. Bockus, M.D., professor of gastroenterology, University of Pennsylvania Graduate School of Medicine, and colleagues. 8°, cloth, 1091 pp., with 427 illustrations. Philadelphia and London: W. B. Saunders Company, 1946. \$11.00.

This last volume of a standard reference system is the joint work of fourteen members of the faculty of the Graduate School of Medicine of the University of Pennsylvania. To each chapter is appended a selective bibliography. The book is well printed on coated paper, which makes it rather heavy for its size. The complete set of three volumes should be in the reference collections of all medical libraries.

Transactions of the American Association of Genito-Urinary Surgeons. Fifty-sixth annual meeting held at Stockholm, Massachusetts, June 8, 9 and 10, 1944. Volume XXXVII. 8°, paper, 315 pp., with illustrations. Saint Paul and Minneapolis: The Bruce Publishing Company, 1945.

NOTICES

BOSTON MEDICAL HISTORY CLUB

There will be a meeting of the Boston Medical History Club in Sprague Hall at the Boston Medical Library, 8 Fenway, on Monday, January 27, at 8:15 p.m. Dr. Merrill Moore will speak on the subject "Medical Experiences in New Zealand and China."

All interested persons are cordially invited to attend the meeting.

GREATER BOSTON MEDICAL SOCIETY

A meeting of the Greater Boston Medical Society will be held in the auditorium of the Beth Israel Hospital on Tuesday, February 4, at 8:15 p.m. Dr. Ephraim Short, associate professor of medicine, Cornell University Medical College, will speak on the subject "Metabolic Aspects of Renal-Secretion Formation and Prevention."

TUFTS ALPHA OMEGA ALPHA

The Tufts chapter of the Alpha Omega Alpha will meet in the auditorium of the Beth Israel Hospital, Boston, on Wednesday, February 26, at 8:30 p.m. Dr. Harry Gold, of the Department of Pharmacology, Cornell University Medical College, will speak on the subject "Cardiac Therapy."

MASSACHUSETTS MEDICO-LEGAL SOCIETY

The midwinter meeting of the Massachusetts Medico-Legal Society will be held at the Magrath Library, Department of Legal Medicine, Harvard Medical School, on Wednesday, February 12, at 2:30 p.m.

PROGRAM

Short Reports of Cases

Two Cases of Fatal Air Embolism. Drs. Andrew D. Guthrie and Walter W. Jetter.
Rapidly Fatal Unrecognized Intestinal Obstruction due to Adherent Meckel's Diverticulum. Drs. Andrew J. Leddy and Richard Ford.
An Unusual Case of Pentobarbital Poisoning. Dr. George D. Dalton and Russell S. Fisher.
Pseudo-Appendicitis incident to Fatal Reaction to Rabies Vaccine. Drs. Peirce H. Leavitt and Angela Lapi.

Discussion of Problems of Procedure

Circumstances in Which the Filing of an Incomplete "Under Investigation" Death Certificate May Be Desirable. Dr. Timothy Leary.
Reimbursement of Undertakers for Transportation of Bodies and Use of Mortuary Facilities. Dr. Leroy T. Stokes.
When and How Should a Medical Examiner Report a Death for Inquest (Section 8, Chapter 38, General Laws)? Dr. David C. Dow.
Business Meeting.
Refreshments.

CORNELL MEDICAL ALUMNI DAY

Alumni Day for Cornell University Medical College will be held on March 13. It will include registration in the morning, with luncheon at the Nurses Residence, to be followed by the business meeting and a schedule of rounds and conferences in all departments. Dinner will be served at the Hotel Roosevelt, and dancing will conclude the day.

THE ROLE OF LANCEFIELD GROUPS OF BETA-HEMOLYTIC STREPTOCOCCI IN RESPIRATORY INFECTIONS*

THE COMMISSION ON ACUTE RESPIRATORY DISEASES†

IT IS widely recognized that Lancefield Group A streptococci are the causal agents in the majority of streptococcal infections in man. In suppurative or generalized infections the role of other groups of streptococci has been established by the isolation of these organisms in pure culture from collections of pus or from the blood stream. In respiratory infections the problem is more difficult, since various Lancefield groups of beta-hemolytic streptococci are found in the oropharynx of normal subjects. Thus, the isolation of one of these groups from the throat of a patient with respiratory disease does not necessarily establish an etiologic relation. Other methods are therefore required to ascertain the relation of the beta-hemolytic streptococcus to the pathologic process.

Previous reports from this laboratory have emphasized the value of serologic tests in the diagnosis of streptococcal respiratory infections. Studies of a food-borne outbreak showed that at least 85 per cent of patients with known streptococcal disease develop either antistreptolysin or antifibrinolysin during the convalescent period¹ and that these antibodies rarely develop in patients who do not exhibit other evidence of streptococcal infection.²

In serologically proved cases of pharyngitis and tonsillitis caused by beta-hemolytic streptococci, certain clinical, bacteriologic and epidemiologic findings have been of value in specific diagnosis. The clinical characteristics include a history of a sudden onset of sore throat, with associated constitutional symptoms, the physical signs of confluent exudate on the tonsils or pharynx, diffuse

injection and edema of the oropharyngeal mucous membranes and enlargement and tenderness of the cervical lymph nodes.

Laboratory studies usually show a polymorphonuclear leukocytosis in such streptococcal infections. Likewise, single or multiple cultures of the oropharynx ordinarily show large numbers of beta-hemolytic streptococci.³ Not infrequently, however, such clinical and bacteriologic findings are misleading, for many patients, with or without exudative tonsillitis or pharyngitis but harboring beta-hemolytic streptococci in the oropharynx, fail to develop specific antibodies during convalescence.^{3,4}

Finally, certain epidemiologic factors have been found to be of value in determining the role of beta-hemolytic streptococci in respiratory disease. It has sometimes been possible to demonstrate a concentration of cases harboring the same group or type of organism.⁵ Cultural surveys in the normal population and in patients with respiratory disease have been particularly valuable. In one study the total incidence and distribution of groups of beta-hemolytic streptococci were identical in normal soldiers and in patients with respiratory disease who did not develop specific antibodies during convalescence.⁴ It was therefore concluded that the majority of patients harboring beta-hemolytic streptococci and failing to develop antibodies were merely carriers of the organisms who had contracted a respiratory infection caused by other agents.

The present study of 3026 cases of respiratory disease was undertaken to determine the role of various groups of streptococci in ordinary respiratory infections. Many of the patients were found to harbor beta-hemolytic streptococci in the oropharynx. Not only Group A organisms but also streptococci of groups B, C, F, G, H and L were encountered. By the use of bacteriologic, epidemiologic, clinical and serologic methods it was shown that infections were caused by Lancefield groups A, C and G and probably also by groups B and F. The various features of the illnesses produced by the different groups of streptococci are described below.

*From the Respiratory Diseases Commission Laboratory (Regional Station Hospital Section 2, Fort Bragg, North Carolina, now located in the Department of Preventive Medicine, Western Reserve University School of Medicine, Cleveland 6, Ohio).

This investigation was aided by the support of the Commission on Acute Respiratory Diseases, Board for the Investigation and Control of Influenza and Other Epidemic Diseases in the Army, Preventive Medicine Service, Office of the Surgeon General, United States Army, and by grants from the Commonwealth Fund, the W. K. Kellogg Foundation, the John and Mary R. Markle Foundation and the International Health Division of the Rockefeller Foundation to the Board for the Investigation and Control of Influenza and Other Epidemic Diseases for the Commission on Acute Respiratory Diseases.

†Members and professional associates of the Commission on Acute Respiratory Diseases are: Lieutenant Colonel John H. Dungey, M.C., A.U.S., director; Lieutenant Colonel Theodore J. Abernethy, M.C., A.U.S., Major George F. Badger, M.C., A.U.S., Major Norman L. Cressy, M.C., A.U.S., A. E. Feller, M.D., Irving Gordon, M.D., Major Alexander D. Legum, M.C., A.U.S., Charles H. Rammekamp, Jr., M.D., Major Eliot Strauss, M.C., A.U.S., and Captain Hugh Tadlock, M.C., A.U.S.

MATERIALS AND METHODS

Source of Cases

The studies were carried out in the Field Artillery Replacement Training Center at Fort Bragg. The soldiers in this organization arrived in large groups from reception centers located throughout the country. At the time of arrival the majority of the men had been in the Army for less than ten days. For a period of eight to seventeen weeks they received basic training and were then transferred to other stations.

The epidemiologic and clinical features of the respiratory infections occurring in this organization will be described in detail elsewhere.⁵ Briefly, each group of recruits observed during the winter months experienced an epidemic of respiratory infections that resulted in the hospitalization of 15 to 30 per cent of the entire organization.* Although the majority of these illnesses were acute, undifferentiated respiratory diseases,⁵ other infections, such as streptococcal tonsillitis and pharyngitis, nonstreptococcal exudative pharyngitis or tonsillitis, influenza A and B, bacterial pneumonia and primary atypical pneumonia, were encountered. In the present study there were few specific contagious diseases.

Between 1943 and 1945 a total of 3026 patients with respiratory infections admitted to the hospital were studied. This included all patients with respiratory infections entering the hospital from selected organizations of recruits during the winter and spring of 1943-1944 and 1944-1945 and 116 consecutive cases of exudative tonsillitis or pharyngitis observed between April and June, 1943.³ The patients were examined soon after admission, and cultures from the throat were obtained. Usually, a second and a third culture were taken from patients who exhibited exudative tonsillitis or pharyngitis or who harbored beta-hemolytic streptococci in the throat as determined by the first culture. An initial sample of blood was drawn at the time of hospitalization, and in 92 per cent of cases, one or more convalescent specimens were obtained three to eight weeks later.

Carrier Surveys

Throughout most of the period of this study carrier studies were carried out in large samples of recruits who were on active duty. These cultural surveys were made between January and May, 1944 and 1945, during which time most of the patients with respiratory infections were studied.*

Laboratory Procedures

The throat cultures were obtained by the swabbing of both tonsils or tonsillar fossas and the posterior pharynx. The swab was either streaked directly on a blood-agar plate† or placed in 3 to 5 cc of

tryptose phosphate broth, and after thorough mixing, 0.1 cc was transferred to a blood-agar plate. The plates were then incubated at 37°C for twenty-four hours, following which they were examined for colonies showing beta hemolysis under a wide-field binocular microscope. In general, only one colony was picked for grouping and typing, unless two distinct types were recognized. The grouping of the beta-hemolytic streptococci was accomplished by the capillary tube-precipitin method, extracts prepared by Fuller's technic⁶ being used. Commercial serums were available for testing groups A, B, C, D, E, F, G, H and L.

The streptococcal antibodies employed in serologic diagnosis were antistreptolysin and antifibrinolysin. Antistreptolysin O titers were determined by a modification of the method of Hodge and Swift.⁷ The technic used to measure antifibrinolysin has been described elsewhere.⁸ The fibrinolysin employed routinely in this test was prepared from a Group A beta-hemolytic streptococcus (No. 98), in a number of cases, however, determinations were also made with streptococci of groups C and G as the source of fibrinolysin. In both tests for streptococcal antibodies the acute and convalescent specimens of serum were examined at the same time. Under these conditions an increase of titer of either antibody of two or more dilution increments during the convalescent period has been shown to be highly indicative of a specific reaction to the streptococcus.⁹ In the present study, therefore, only changes of this magnitude demonstrated within a period of eight weeks—usually within three weeks—were considered significant.

CULTURAL SURVEYS

The frequency with which the various Lancefield groups of streptococci were found in the oropharynx of normal soldiers and in patients with respiratory infections admitted to the hospital is shown in Table 1. The carrier rates for all beta-hemolytic streptococci in the normal soldiers varied between 8.0 and 9.7 per cent, averaging 8.9 per cent. The rate among patients hospitalized for respiratory disease was 13.9 per cent.

The 5 per cent difference between these rates is largely accounted for by the fact that Group A streptococci were isolated more frequently in the soldiers with respiratory infections than in healthy soldiers. This organism was obtained in the former in 9.5 per cent, and in the latter, in 5.4 per cent—a difference of 4.1 per cent. These data suggest that Group A streptococci were responsible for the majority of the streptococcal infections.

Lancefield groups B, C, F and G were isolated from the oropharynx of both healthy subjects and hospitalized patients, whereas streptococci of groups D, E and H were not found. In the hospitalized soldiers, a Group L streptococcus was isolated from 1 patient at the time of admission. With the excep-

*A soldier with respiratory disease was hospitalized if the oral temperature was over 100°F.

†All blood agar plates contained 0.005 per cent para-aminobenzoic acid.

on of Group A, there were no significant differences in the carrier rates of these various Lancefield groups between the normal soldiers and those hospitalized with respiratory disease. These data indicate that the organisms did not play an important role in the respiratory infections studied. It cannot be concluded, however, that no infections were caused by these streptococci.

SEROLOGIC STUDIES

As pointed out above, the isolation of beta-hemolytic streptococci from the throats of patients with respiratory disease does not necessarily indicate causal relation, and this point is emphasized by the fact that the same organisms were recovered

cultured at weekly intervals. A second specimen of blood was taken three to eight weeks later. Antibody determinations on these sets of serum disclosed that of 236 soldiers who did not harbor beta-hemolytic streptococci, none developed antibodies.² There were 45 subjects who harbored Group A organisms without illness, 1 of whom developed antibodies. In sets of serum collected from 37 soldiers harboring Group C streptococci at some time during the three to eight weeks of study, an increase in the antistreptolysin titer was demonstrated in 1 case. This soldier did not enter the hospital, nor was he seen in the local dispensary. Three of four cultures of the throat taken between the two samples of blood showed Group C streptococci. There was no

*Admission cultures

from normal soldiers. The number of streptococcal infections occurring in the hospitalized soldiers may be estimated by differences between the carrier rates in the normal and hospitalized soldiers; such studies, however, do not disclose the person who is infected with the organism. It is necessary, therefore, to use other methods to establish the validity of a diagnosis of a streptococcal respiratory infection in the individual patient.

A serologic diagnosis of streptococcal infection was accomplished by the demonstration of an increase in the antistreptolysin or antifibrinolysin titer of the serum obtained during convalescence. Streptolysin O is produced by organisms belonging to Lancefield groups A, C, and G,⁹ and fibrinolysin is produced principally by the same groups, although a few strains of other groups have been observed to cause lysis of fibrin clots.¹⁰ Thus, these two antibody tests are at present considered to be of value only in the diagnosis of infections caused by streptococci of groups A, C and G.

To evaluate the results of the antibody determinations in the hospitalized patients, it was first necessary to establish the frequency with which an increase in titers of antistreptolysin or antifibrinolysin occurred in the normal population. For this purpose a serum specimen was obtained from soldiers on active duty, following which the oropharynx was

significant change in antibody titer in sets of serum collected from 35 soldiers harboring Group G streptococci.

These results demonstrated that in the population studied streptococcal antistreptolysin and antifibrinolysin did not develop in the absence of beta-hemolytic streptococci; moreover, such antibodies were rarely demonstrated in the serum of normal soldiers who harbored these organisms.

Serums taken during the acute and convalescent phases were available for study from 429—92 per cent—of the 465 hospitalized men who harbored beta-hemolytic streptococci in the oropharynx in any of three throat cultures. Of the 429 patients, 161, or 37.4 per cent, developed specific antibodies during the period of convalescence (Table 2). The majority of the increases in antibodies were observed in serums collected from patients harboring Group A streptococci. Of the sets of serum from patients with Group A streptococci alone, approximately half exhibited an increased titer during convalescence, and 39 per cent of patients with Group A in combination with some other group developed antibodies. Of 43 patients with Group C and 41 with Group G streptococci, 16 and 12 per cent, respectively, developed antibodies during the convalescent period. One patient from whom Group L was isolated developed antibodies.

Since the demonstration of an increase of anti-streptolysin or antifibrinolysin titer during early convalescence is a highly specific test² and since such increases were rarely observed in the normal populations studied, it is concluded that the demonstration of a significant increase in these antibodies

were isolated from 86 per cent, and Group A alone or in combination with other groups accounted for 90 per cent. The remaining 10 per cent of cases occurred in patients harboring other groups, the largest being Group C with 7 patients, or 4 per cent of this total. Group G was isolated in 3 per cent of the infections.

EPIDEMIOLOGIC, CLINICAL, BACTERIOLOGIC AND IMMUNOLOGIC STUDIES

A detailed study was made of the cases of respiratory disease in which beta-hemolytic streptococci were recovered from the oropharynx. The purpose

of this investigation was not only to establish the relation of the different Lancefield groups to the individual infection but also to describe the response of the host to such infections.

Group A

The difference in the carrier rates of Group A beta-hemolytic streptococci in the normal soldiers and the patients hospitalized for respiratory disease indicated that 124 (41 per cent) of the 3026 cases had been caused by this organism. Serologic studies showed that 139 patients had an infection due to Group A streptococci as determined by the demonstration of an increase in the antistreptolysin or antifibrinolysin titer during convalescence.

The serologically proved infections occurred essentially in a sporadic fashion, only a few small, localized outbreaks caused by a single type of Group A streptococcus were recognized.

Among the 139 patients who harbored Group A streptococci and developed antibodies 101, or 73 per cent, had exudative tonsillitis or pharyngitis. By contrast, the incidence of exudative lesions of the throat in the patients who harbored Group A organisms but failed to develop antibodies was only 34 per cent.

Clinical and laboratory data obtained on patients with exudative tonsillitis and pharyngitis due to Group A streptococci have been presented elsewhere in detail.³ These patients usually complained of soreness of the throat and such constitutional symptoms as feverishness, chilliness, headache and anorexia. Inspection of the throat showed that the exudate was usually discrete to confluent and that the mucous membranes were diffusely injected and somewhat edematous. The regional lymph nodes were likely to be enlarged and tender. The average white-cell count was 16,000, and cultures of the throat showed that Group A streptococci predominated in approximately half the patients. The course of the illness was short, the symptoms usually disappearing by the fourth or fifth day.

The patients who did not have exudative lesions in the throat were seldom thought to have had streptococcal infections when examined at the time of admission. A diagnosis of the specific nature of the illness was possible only after bacteriologic and serologic studies had been completed.

Group B

Six patients were found to harbor Group B streptococci. As expected, an increase in antistreptolysin or antifibrinolysin titer during convalescence was not demonstrated in the serum of the 5 patients tested, since Group B streptococci do not produce streptolysin or fibrinolysin.

There was no evidence of focal concentration of the cases, which occurred sporadically throughout the three-year period. Three of the patients were thought to have undifferentiated acute respiratory

ase⁵ The remaining 3 patients had exudative illitis. In 1 case all three cultures yielded up B streptococci, and in one culture this organism accounted for more than 50 per cent of the ones. The total white-cell count in this patient was 13,600. The second patient had discrete areas of exudate on both tonsils, as well as considerable redness of the soft palate. The lymph nodes were not enlarged or tender. Only one of three cultures yielded Group B streptococci, and the white-cell count was 14,200. The third patient with exudative illitis showed diffuse redness and swelling around

time of admission to the hospital, 6 patients complained of a sore throat. In 3 cases inspection showed areas of discrete exudate on the tonsils. The maximum temperature recorded during hospitalization varied from 99.4 to 103.4°F, and the course of illness was similar to that of a mild streptococcal infection.³ In the majority of cases the temperature became normal within seventy-two hours.

The laboratory studies showed that the average total white-cell count was 10,735. In the 3 patients who had exudative lesions on the tonsils, the total

the tonsil, so that a diagnosis of peritonsillitis was made. The regional lymph nodes were enlarged and tender. The white-cell count was only 8,600. A course of penicillin therapy resulted in recovery without abscess formation.

The clinical evidence thus suggested that 3 patients had a respiratory infection caused by the Group B streptococcus. These patients exhibited exudative lesions on the tonsils, 1 developed peritonsillitis, 1 showed enlarged and tender lymph nodes and in 2 the total white-cell count was elevated.

Group C.

The carrier rate for Group C streptococci in the normal and in the hospitalized soldiers was practically identical, being 1.4 and 1.8 per cent respectively. These figures indicated that the majority of the patients were merely carriers and did not have a true streptococcal illness. This was confirmed by the serologic studies, which showed that only 7 hospitalized subjects harboring Group C streptococci developed antibodies during convalescence (Tables 2 and 4).

The illnesses in these 7 patients occurred sporadically throughout the entire period of study. At the

time of admission to the hospital, 6 patients complained of a sore throat. In 3 cases inspection showed areas of discrete exudate on the tonsils. The maximum temperature recorded during hospitalization varied from 99.4 to 103.4°F, and the course of illness was similar to that of a mild streptococcal infection.³ In the majority of cases the temperature became normal within seventy-two hours.

The serums of all 7 patients showed a significant increase in antistreptolysin titer during the convalescent period, but in only 1 subject (Case T-101) did the antifibrinolysin titer increase significantly. Several of the sets of serum (Cases T-101, O-258, O-522, O-581 and O-1070) were tested with fibrinolysin obtained from Group C as well as from Group A streptococci, and no essential difference was observed in the antibody titer. An increase in streptococcal antibodies was demonstrated within twenty-seven days following admission to the hospital in 6 patients. Thus, the clinical and laboratory studies, as well as the bacteriologic and serologic findings, indicated that the majority of the 7 cases presented in Table 4 represented infection by Group C streptococci.

The temperature chart of one of these patients (Case O-581) is presented in Figure 1. This eighteen-

patients harboring Group G streptococci developed antibodies during convalescence. A summary of the data in these cases is presented in Tables 2 and 5. All but 1 of the patients complained of a mild sore throat at the time of the first interview, and in

swollen tonsils on which areas of discrete exudate were present. The cervical lymph nodes were small and not especially tender. Cultures on three successive days showed Group G streptococci. The antistreptolysin titer on admission was 125, and on the twenty-fifth day was 250. Antifibrinolysin determinations were made with the use of both Group A and Group G streptococci as the source of fibrinolysin. The titer with both fibrinolysins, which had been less than 25 units on the initial serum specimen, had increased to only 25 units on the twenty-fifth day.

Case O-694 is of interest since the increase in antistreptolysin titer was demonstrated on the thirteenth day of illness. The titer of serum specimens obtained twelve and nine days before admission was 63 units of antistreptolysin. Also, cultures of the throat obtained thirteen, twelve and one days prior to admission showed Group G streptococci. It therefore appears that the increase in antistreptolysin titer was due to this organism. No increase in titer to fibrinolysins of groups G, C and A was demonstrated in the serums obtained from this patient.

The first two cultures in Case O-971 showed Group G streptococci, and the antistreptolysin titer increased from 250 to 500 units in thirty days. Previous specimens of blood obtained fifteen and fifty-seven days prior to admission to the hospital showed a titer of 250 units. There was no change in the antifibrinolysin titer when tested by fibrino-

FIGURE 3 Clinical Chart of a Patient with a Group G Streptococcus Infection.

In 1 case exudate was present on the tonsils. The maximum oral temperatures observed during the course of these illnesses varied from 100.8 to 103°F. The temperature became normal within two days in 4 cases, and in 1 it reached a normal level within three days.

year-old soldier developed a nonproductive cough and mild coryza a week prior to admission to the hospital. Five days later he noticed a sore throat, as well as slight chilliness without a true rigor

coccal illness. Seven patients* were found to have exudative tonsillitis or pharyngitis. The temperature curves, throat cultures and white-cell count are presented in Figure 2. Three patients (Cases

FIGURE 1 Clinical Chart of a Patient with a Group C Streptococcus Infection

Inspection of the throat showed that the tonsils and surrounding tissues were diffusely injected, with areas of discrete exudate on both tonsils. The cervical lymph nodes were large and tender. The white-cell count on the second hospital day was 15,600, with 69 per cent neutrophils. The antistreptolysin titer increased from 200 to 400 units in twenty-six days, but no increase in antifibrinolysin was demonstrated in tests made from either Group A or Group C streptococci.

Group F

Eleven patients with respiratory illnesses were found to harbor Group F streptococci in the throat, and all these patients entered the hospital in March and April, 1944, when 857 patients admitted to the hospital were studied; there was no other evidence that these cases occurred in an epidemic fashion, since all the soldiers were housed in different barracks. A survey of the carrier rate for beta-hemolytic streptococci made during the same period showed Group F organisms in only 2, or 0.12 per cent, of 1568 soldiers on active duty. On the basis of the first hospital culture, 3, or 0.35 per cent, of 857 patients harbored the organism.

In the hospital 6 patients were housed in one ward, and 4 in another. This suggested the possibility of cross infection in the hospital; examination of the dates of admission and discharge, however, revealed that cross infections were unlikely in the majority of cases.

There was some clinical evidence that a few of the patients with Group F streptococci had a strepto-

coccal illness. Seven patients* were found to have exudative tonsillitis or pharyngitis. Several showed a rather brisk febrile response.

In only 2 patients were Group F streptococci isolated in all three cultures; in 3 others, two cul-

FIGURE 2 Temperature Charts of Eleven Patients with Respiratory Infections Who Harbored Group F Streptococci in the Oropharynx

tures showed this organism. The white-cell count was slightly elevated in only 2 patients (Cases E-426 and E-223).

*Cases B-84, B-164, E-390, E-426, E-471, E-223 and E-531

tain selected organizations of recruits but also surveys among the healthy soldiers in the same organizations. Thus, the differences in the prevalence of beta-hemolytic streptococci among the healthy soldiers and those hospitalized with respiratory disease should indicate the group or groups responsible for the illnesses. The carrier rate for all beta-hemolytic streptococci in the healthy soldiers was about 9 per cent, whereas 14 per cent of the hospitalized soldiers carried these organisms. The difference in rates was due almost entirely to Group A streptococci.

By the additional use of serologic, clinical and epidemiologic data, segregation of the specific patients with respiratory illness due to the beta-hemolytic streptococcus was possible. That such a method was valid was shown in a previous study⁴ and again by the data presented above. If all the hospitalized patients who developed either antistreptolysin or antifibrinolysin during convalescence were excluded from the cultural surveys, the carrier rates in the healthy and hospitalized soldiers were approximately the same. This indicates that the beta-hemolytic streptococci in the oropharynx of the majority of the patients with respiratory illness who did not develop antibodies were not causally related to the infectious process.

On the basis of the demonstration of antibody formation during the convalescent period, 38 per cent of all cases of respiratory disease that showed beta-hemolytic streptococci were cases of streptococcal infection. At this Army hospital, beta-hemolytic streptococci were recovered from 465 of 126 patients with respiratory infections. Thus, serologically proved cases of streptococcal disease accounted for approximately 6 per cent of the respiratory admissions in recruits over a three-year period. It is to be emphasized, however, that during this period there were no large epidemics and that the majority of streptococcal illnesses occurred sporadically.

The serologic reactions observed in the serums collected from these patients harboring different Lancefield groups of beta-hemolytic streptococci were of considerable interest. Streptolysin O is known to be produced only by organisms belonging to groups A, C and G.⁹ It is well established that Group A infections are followed by an increase in the antistreptolysin titer in the majority of cases. Antibody studies have rarely been employed in the analysis of infections caused by other groups. Kirby and Rantz¹⁴ described an increase in antistreptolysin in the serum of a patient with bacteremia due to a Group C streptococcus. In the present study 7 patients harboring this organism and 5 with Group G streptococci developed antistreptolysin during convalescence. Longcope¹⁵ studied a thirteen-year-old boy with an infection due to the Group F streptococcus whose serum exhibited an increase in antistreptolysin titer. No case of a rise in these anti-

bodies, however, was observed in the 11 patients harboring Group F strains reported above.

The antifibrinolysin response to infection by streptococci belonging to Group A have been described elsewhere.¹⁶ In that study a correlation was demonstrated between the ability of the homologous strain to produce fibrinolysin *in vitro* and the occurrence of an antifibrinolysin response following infection. In the present study 1 of the 7 patients with infections due to Group C organisms and none with infections due to those of Group G exhibited a significant increase in the antifibrinolysin titer. This low incidence of antifibrinolytic response was expected, since both organisms usually produce less fibrinolysin than Group A.¹⁰ The median *in vitro* production of 452 Group A strains was 117 units, of 137 Group C strains, 61 units, and of 104 Group G strains, 20 units of fibrinolysin.

In several of the patients with infections due to groups C and G the serums in the acute and convalescent phases were tested with fibrinolysin made from Group A, Group C and Group G streptococci. With the use of quantitative methods,⁸ no significant differences in the titers of antifibrinolysin were demonstrated with these three preparations. These results, as well as those of a more detailed study,¹⁷ show that fibrinolysins produced by beta-hemolytic streptococci of groups A, C and G are immunologically identical. Kirby and Rantz¹⁴ found that the antifibrinolysin titer following an infection with Group C was approximately the same when measured by either Group A or Group C fibrinolysin. They suggested that, from a qualitative standpoint, these fibrinolysins are similar.

On the basis of serologic tests, 90 per cent of the streptococcal illnesses were due to Group A, 4 per cent to Group C and 3 per cent to Group G. A detailed study of the infections caused by streptococci of groups A, C and G failed to show any outstanding differences in the clinical pattern. The illnesses produced by each group were mild and of short duration. A few of the infections included as cases of infection with Group C or G may have been due to Group A, since in some the number of cultures obtained were not adequate to rule out the presence of the latter organism.

The role of beta-hemolytic streptococci of groups B, F, H and L in the respiratory illnesses could not definitely be ascertained. There was some clinical evidence that groups B and F occasionally produce an infection, since several patients exhibited such clinical features as a discrete exudate over the tonsils, diffuse redness and edema of the soft palate, tonsils and pharyngeal mucosa and enlargement and tenderness of the cervical lymph nodes.

SUMMARY

A study undertaken to show the importance of the Lancefield groups of beta-hemolytic streptococci in mild respiratory infection is reported. In a large

lysins prepared from Group A, Group C and Group G streptococci

In Case E-549 only one culture was positive for Group G streptococci, but the antistreptolysin titer increased within nineteen days after admission to the hospital. Case B-8 also had only one culture that showed a Group G streptococcus. This patient entered the hospital because of weakness, chilliness and feverishness of two days' duration. The only respiratory symptoms were sneezing, coryza and a slight cough. Seven days after entry, the patient was discharged from the hospital, only to return two days later, when a blood specimen showed that the antistreptolysin titer had increased from 125 to 159 units. Cultures of the throat and sputum again showed Group G streptococci. A throat culture taken twelve days after the first admission showed a Group A, nontypable streptococcus. It seems probable, although not definite, that the illness in this patient was due to Group G, since an antibody response had occurred prior to the isolation of the Group A organism.

Thus, 5 of the 41 patients with respiratory disease who harbored Group G streptococci in the oropharynx exhibited serologic evidence of a streptococcal infection (Table 5). It is of some interest that only 1 of these patients had exudative tonsillitis. The white-cell count was not elevated in the 4 patients examined.

Group H

The patient who harbored Group H streptococci showed the organisms in only one of three cultures. This patient had exudative tonsillitis and pharyngitis. There was little injection around the areas of exudate, however, and the cervical lymph nodes were not enlarged or tender. The white-cell count was 5500.

Group L

The patient who harbored Group L streptococci in the throat and developed antibodies during convalescence entered the hospital because of feverishness, cough, hoarseness and nasal discharge. He appeared only mildly ill, and the oral temperature was 101°F. The soft palate was slightly edematous but not injected. The tonsils had been removed. The pharynx showed only slight redness, and the cervical lymph nodes were neither enlarged nor tender. Fine rales were heard over the right lower posterior portion of the chest, and a roentgenogram showed a small area of pneumonia above the right diaphragm. The white-cell count was 15,800. The only throat culture obtained was at the time of admission, Group L streptococci were identified. After two days in the hospital the temperature became normal, and the pulmonary infiltration disappeared by the sixteenth day. The clinical diagnosis was primary atypical pneumonia.

The antistreptolysin titer measured 200 units on admission, 250 units on the fourteenth day and 317 units on the twenty-ninth day. The antifibrinolysin titer, which on admission was 100 units, was 200 units fourteen and twenty-nine days later. Since there is no information whether Group L streptococci produce streptolysin or fibrinolysin, and since adequate cultures were not obtained to rule out the presence of some other group, it was impossible to determine if this illness was due to Group-L streptococci.

DISCUSSION

With the exception of scarlet fever and puerperal infection, information concerning the importance of the different Lancefield groups of beta-hemolytic streptococci in various types of infections is meager. Scarlet fever is rarely caused by streptococci of groups other than Group A. Hare,¹¹ in a summary of several investigations, reported that 115 patients with scarlet fever showed Group A streptococci and that in 2 cases the grouping was unknown. Gardner¹² isolated a Group G and a Group F streptococcus respectively from 2 of 21 patients with the disease.

Apparently beta-hemolytic streptococci of groups other than Group A are frequent causative agents in puerperal fever and septic abortions. In Hare's¹¹ summary of 206 patients with these infections, 3 cases were caused by Group B, 3 by Group C and 1 each by groups D and G and ungrouped organisms, the remainder being associated with Group A streptococci. Hill and Butler¹³ reported 110 cases of beta-hemolytic streptococcus infection of the uterus, 82 of which were caused by Group A, 12 by Group B, 10 by Group C and 6 by Group G. Thus, approximately 25 per cent of these patients had infections caused by beta-hemolytic streptococci not belonging to Group A.

In erysipelas there is some indication that Group C plays a significant role, since in 28 cases studied, this organism was isolated in 5 cases.¹⁴

Further data indicating the importance of streptococci of groups other than Group A are obtainable only from isolated case reports and cultural surveys of hospitalized patients. The report of one or several cases—or even of an occasional epidemic—due to the rarer groups of beta-hemolytic streptococci is of little aid in the estimation of the frequency with which the various groups cause disease. Likewise, reliable data are difficult to obtain from reports on cultures obtained from hospitalized patients with various types of infections, since the isolation of one of the groups of streptococci, especially from the oropharynx, does not necessarily indicate a causal relation to the pathologic process.

In the present study several sources of information were used to determine the role of the groups of beta-hemolytic streptococci in respiratory infections. These included not only cultures of all patients with respiratory infections admitted to the hospital from

extremely narrow, it is easy to maneuver, and there is less danger of destroying surrounding structures

The usual type of Achilles shortening found in my patients may be attributed in the main to lists applied to the lower extremity with the foot in some degree of plantar flexion. Also, following compound comminuted fractures, even though the foot has been encased in plaster in a neutral position, the tendon or belly of the gastrocnemius muscle becomes scarified and tends to contract, with subsequent shortening. Occasionally, after peroneal lacerations, patients fail to wear dropped-foot or night

The operative procedure is illustrated in Figure 2. The lower extremity is properly draped. A blood-pressure cuff may be applied about the midhigh level and inflated to a pressure equivalent to 600 mm of mercury, but its use is optional. The plantar surface of the foot is then placed against the abdomen of the operator, so that the Achilles tendon is stretched. Thus, both hands of the surgeon are free to carry out the procedure, and at the same time, tension of the tendon is maintained. With the use of the fingers of one hand to estimate the approximate width of the tendon, a stab wound on

FIGURE 2 Diagrammatic Representation of the Operative Procedure in Triple Hemisection of the Achilles Tendon

splints, with the result that a shortened tendon often develops. These conditions are opposed to the usual civilian type of postpoliomyelitis in which muscle imbalance results in shortening of the Achilles tendon.

White has described one of the main problems in elongating the Achilles tendon as follows: "The explanation of the difficulty encountered in lengthening the heel cord by simple subcutaneous tenotomies lies in the fact that there is approximately a ninety-degree twist of the structure on its own axis within the surgical field, and that when even two thirds of the medial fibers have been severed at one level and two thirds of the lateral fibers at another level, enough fibers miss being cut to cause the tendon to 'hang'." This statement describes the tendinous arrangement most adequately. This anatomical fact regarding the tendon of the gastrocnemius muscle is not, however, well known and bears repetition.

the medial aspect of the extremity is made into the substance of the tendon about 2.5 cm superior to its insertion into the calcaneal tuberosity, with the flat of the knife blade on the same plane as the longitudinal fibers of the tendon. Greater success is assured if, when the tip of the blade has pierced the tendon, its course is altered from a simple transverse to a posterolateral direction. Because of the twist in the Achilles tendon, as demonstrated by White, at least a third of the tendon at this level must be divided. Caution must be taken to follow the medial approach, which alone gives assurance that the posterior tibial nerve or vessels will not be injured. This point cannot be too strongly emphasized.

Once the operator is certain that the point of the blade has passed through to the lateral aspect of the tendon, the knife is turned through an arc of 90° in an anterior direction. Provided that this maneuver

Army camp, only 6 per cent of cases among patients admitted to the hospital from an organization of new recruits were due to streptococcal infections. Bacteriologic and immunologic studies demonstrated that 90 per cent of the infections were due to Group A, 4 per cent to Group C and 3 per cent to Group G. Clinical and epidemiologic evidence suggested that a few patients had infections due to groups B and F.

The illnesses produced by the various groups of beta-hemolytic streptococci were similar. Streptolysin O antibodies were demonstrated in serum specimens obtained from patients harboring organisms of groups A, C and G. Antifibrinolysin developed in patients with infections due to Group A and Group C streptococci. The titer of antifibrinolysin in the serum specimens taken during the acute and convalescent phases from patients with infections due to groups C and G was identical when measured with fibrinolysin prepared from organisms of groups A, C and G.

TRIPLE HEMISECTION: A SIMPLIFIED PROCEDURE FOR LENGTHENING THE ACHILLES TENDON*

LIEUTENANT COLONEL RAFE NELSON HATT, M.C., A.U.S., AND MAJOR TIMOTHY A. LAMPHIER, M.C., A.U.S.

ABOUT twenty years ago, a new procedure for lengthening the Achilles tendon was first employed. It is known as triple hemisection. Dr. Michael Hoke, who is believed to have been the first to use this simplified technic, did not publish his results. And yet, according to White,[†] "lengthening the heel cord is the commonest single operative procedure in the repertoire of most orthopedic surgeons, and the reporting of any simplification of the technique seems justified."

Our purpose in describing this operation is to re-emphasize its simplicity. Excellent results have been obtained without the necessity of using the so-called "open tenoplasty technic." Certainly, the much shorter operative time alone indicates triple hemisection of the Achilles tendon as the procedure of choice. Surgical exposure of a large portion of a tendon or of any internal structure necessarily carries with it the possibility of postoperative sepsis. Even the availability of such new drugs as penicillin and

streptomycin does not mean that infection of tendon sheaths is easy to control. Another and even more important consideration is that the continuity of the tendon is maintained.

A so-called "tenotome" (Fig. 1), is used in this procedure. Its outstanding feature is a narrow thin blade that requires only a minute puncture hole in

FIGURE 1 Photograph of Tenotome

the skin prior to piercing the substance of the tendon. Once the knife has been inserted into a tendinous structure, there is no danger that the blade will be separated from the handle. Since the blade

lengthening and thus to correct the greater degree plantar flexion

One criticism of this technic is that the ruptured bers tend to become adherent to surrounding ructures. This has not happened, however, in the undreds of lengthening procedures carried out as escribed above. Certainly, the open tenoplastic

procedure traumatizes and exposes a greater amount of subcutaneous structures than the simpler triple hemisection. One of us (R N H) has had the opportunity to use this technic frequently during the past twenty years. The results obtained have been excellent and confirm the value of this simple method

PRURITUS ANI*

NEIL W SWINTON, M.D†

BOSTON

A REVIEW of the voluminous literature on the subject of anal pruritus reveals that nearly as many theories regarding the etiology of this condition have been advanced and methods of treatment advocated as there have been authors. Several conclusions might be taken from this. First, the final answer has not been written, and there may be several etiologic factors involved in many of the patients with this condition. Secondly, because so many preliminary good results have been reported following so many apparently different types of therapy directed primarily toward the perianal region, the treatment of the patient, in addition to the management of the local anorectal condition, may be an important factor. Thirdly, there may be a factor common to many of these apparently different types of treatment that has been overlooked by the attention given the variety of drugs, injections and surgical procedures used on the perianal area.

The fact that many of these methods are not permanently successful is apparent in that a large number of the patients seen at the Lahey Clinic have already had some type of local anorectal therapy for anal pruritus without more than temporary relief.

It is not the purpose of this paper to announce that a cure for every patient with anal pruritus has been discovered or to present a long statistical study, but it is a condition that is often seen and one in which we have been particularly interested for several years. Many of the studies reported in the literature have not been carried out, and there are many types of treatment that we have not utilized, it is a frequent complaint, however, and many of the intractable cases present serious and complicated problems.

As a result of this experience we have developed certain theories regarding the etiology of this condition and methods of treatment. It is the purpose

of this presentation to discuss the factors that may give rise to anal itching or may cause an anal pruritus to become an intractable and definite pathologic entity, and to present the methods of treatment that have proved most satisfactory.

ETIOLOGY

Some precipitating factor begins an anal pruritus. An anal itching is often noticed following a period of diarrhea or constipation, particularly if there is some associated anorectal disease. It is also a frequent observation that fatigue, worry and nervous tension are associated. Usually, this itching is transient and causes only mild and temporary discomfort.

The natural tendency for relief of an anal itch is to rub or scratch, which, if continued, causes local congestion, trauma and irritation and allows the introduction of infection into the perianal skin and adjacent tissues. This, in turn, causes more itching and sufficient excuse for further scratching and irritation of the part. Thus, a cycle of scratching and itching is established that, in the long-standing, intractable case, may develop into such a habit fixation that the patient is powerless to let himself alone and is awakened from a sound sleep, scratching himself.

This scratch-itch syndrome is a basic factor in the background of a large number of patients with an intractable anal pruritus and must be thoroughly appreciated by both the physician and the patient. Patients with an intractable condition of this type who have been treated by several physicians with various remedies often state that no one had ever taken the time to emphasize the importance of the avoidance of irritation to the parts affected. It is my belief that many of the intractable cases would never have developed if this single principle had been followed in the early stages of the disease.

Scratching is not the only cause of pruritus ani—it is an important factor, particularly in intractable cases, but it must not be overlooked that something additional caused the original itch. In

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 21, 1946.

†Surgeon, New England Baptist, New England Deaconess and Massachusetts Women's hospitals; surgeon, Lahey Clinic.

has been carried out properly, approximately one third of the tendon will have been divided.

When a second operative site, about 2.5 cm above the original stab wound, has been selected, the tenotome blade is again passed by a medial approach through the skin and into the substance of the tendon. The course of the blade is again altered from a simple transverse to a slightly antero-lateral direction. After the operator has determined that the tip of the blade is felt subcutaneously on the lateral aspect of the extremity, the blade is rotated through an angle of 90° posteriorly, and again approximately one third of the structure will have been divided.

The third — or most proximal — puncture wound is made about 2.5 cm above that just described, the tenotome blade passing through the substance of the tendon in a posterotransverse direction. Again, the blade is turned through an angle of 90° anteriorly, and the operator is conscious that the fibers have been divided.

The next maneuver consists in the exertion of greater pressure against the plantar surface of the foot opposite the metatarsal heads. The weakened tendon, which relaxes as the fibers slide apart, can be lengthened until the foot is dorsiflexed to an angle greater than 90° . One should not be too enthusiastic in obtaining a markedly acute angle in dorsiflexing the foot, since the tendon may be completely divided and its continuity lost.

The entire procedure can be completed within a few minutes by an experienced operator. The assurance that the continuity of the tendon has been maintained is of primary concern. The results obtained by this simple method leave open to doubt the desirability of other, more prolonged procedures.

After the dorsiflexion of the foot to the desired angle, the three puncture wounds are dressed with sterile gauze. Sutures are entirely unnecessary, for the wounds are so small that the skin edges do not require approximation. With the foot maintained in the dorsiflexed position at all times and with the leg fully extended to 180° at the knee joint, the extremity is encased in plaster from the toes to the lower thigh level. Jack-knifing of the extremity at the knee joint while the cast is being applied must be avoided, to maintain tension on the Achilles.

An inexperienced operator may completely bisect the tendon, and when this occurs, a modified open tenoplastic repair must be resorted to.

Postoperatively, the cast is not removed in less than four weeks, to prevent recurrent shortening of the tendon. From the fifth through the eighth week the patient is allowed to remain ambulatory during the day, but a posterior plaster shell or a so-called "night ladder splint" should be worn while the patient is sleeping.

The double-exposure photographs (Fig. 3) represent the degrees of dorsiflexion before and four weeks after operation. Shortening of the Achilles tendon

in this case resulted because the patient had previously had a cross-leg skin flap applied to his heel and the foot had been left in a flexed plantar position for several weeks.

* * *

The triple hemisection method of Dr. Michal Hoke for lengthening the Achilles tendon has been described in detail. Difficulties arise in attempting

FIGURE 3 Double-Exposure Photographs Showing the Degree of Dorsiflexion before (upper) and after (lower) Operation.

the procedure in cases in which unsuccessful subcutaneous tenotomy has been attempted at some previous date. Occasionally, inexperienced operators attempt to gain too great an angle of dorsiflexion and completely disrupt the tendon. It should be remembered that, in marked deformities, the puncture wounds of the heel cord should be proportionately separated farther apart to obtain greater

combat zone. The majority of these men, experienced infantrymen, had the highest morale and were too busy and occupied most of the time to develop an anal fixation and spend their time worrying and itching and scratching. It must be remembered that these men were frequently without baths or clean clothes for days at a time and were in a hot, humid climate.

Mechanical Factors

Nearly every case of anal pruritus is precipitated by some local mechanical factor. If this itching begins when certain other favorable factors exist and relief is not obtained, the condition may become intractable.

Minor trauma to this area is not unusual. The act of defecation may cause an abrasion or a fissure. The effects of instrumentation, rubbing or scratching may begin an itch. Hemorrhoids may be responsible, but probably less frequently than has been believed. Large skin tags, however, by rubbing together, causing congestion and interfering with mechanical cleanliness of the area, often seem to be important.

A contracted anal ring, a condition referred to in the literature as pectenosis, is a frequent factor. Infected or inflamed crypts are rarely involved, in our experience.

TREATMENT

A general physical examination, including an anoscopic and proctoscopic examination of the lower bowel, should be done in all cases. Routine blood counts and a urine examination should be carried out. In the majority of cases, after examination, the cause will be obvious, and the treatment apparent. In many, however, further laboratory and roentgenologic studies will be required and possibly the help of the dermatologist, internist, gastroenterologist or psychiatrist. It is to be noted that the original or precipitating factor in the long-standing case of anal pruritus may have disappeared and, from the standpoint of therapy, may not be particularly significant.

For constitutional treatment, the most important requirements are adequate rest, relaxation and relief from tension. Hospitalization and temporary but adequate sedation may be necessary in severe cases. A small amount of a combination of a tincture of belladonna and luminal, particularly when there is an associated spastic colon, is a helpful sedative. Chloral hydrate ensures a good night's sleep. A normal bowel function should be established as early as possible, and the intake of carbohydrate, excess roughage and alcohol should probably be reduced.

Excessive sweating, which may be troublesome, is the only indication for radiation therapy, since in our experience cases in which such therapy was used routinely nearly all recurred after a period of six

to eight months of temporary relief, and it was found that they were invariably much more difficult to control. We have observed cases in which cancer developed in the anal area from the excessive use of radiation therapy. At the present time it is rarely used.

The presence of seborrhea, psoriasis, eczema, contact dermatitis and certain other strictly dermatologic conditions should not be overlooked. Special studies, particularly for food allergies, may be necessary in certain stubborn cases.

In considering local therapy, we are in entire agreement with Stokes that too much attention has been given to this phase of the management of the patient with anal pruritus. Most patients with long-standing intractable anal pruritus have had one or more series of radiation treatments, undercutting operations or alcohol injections, hemorrhoidectomy, cryptectomy, rectal dilatation or some other surgical procedure. They present a scarred anal ring and perianal area that has obviously been made worse by such treatment. Many of these patients had never been instructed to keep themselves clean and stop scratching.

Several years ago, while doing an alcohol injection on a patient with anal pruritus, I found a visitor very much interested in the procedure and in the disease. She was a missionary who had been in charge of a hospital in India for many years and had never seen a native with an anal pruritus of the type described in the literature, the explanation, in her opinion, being the fact that the Indians had never known modern toilet tissue and merely washed themselves frequently. Certainly, adequate local hygiene is the basis of any local therapy for anal pruritus. That this is not the only factor, however, was borne out by my experience in the Army referred to above.

Our patients are routinely advised to wash themselves often with cotton moistened in warm water and to eliminate toilet tissue and soap. They are instructed never to touch themselves with their fingers or any object other than cotton. The ensuing dryness and cleanliness and the avoidance of trauma will indefinitely control many of the mild cases of anal pruritus.

Among the local medications, potassium permanganate, in a strength of 65 mg to 1 liter of hot water, is used almost routinely. Patients with a mild pruritus are instructed to sit in a basin of this solution for fifteen to twenty minutes at a time as often as is necessary to control the itching. The usual cause of failure in the use of potassium permanganate has been that the solution has not been employed for a sufficient period. The application of a 1 per cent solution of phenol in calamine lotion may be all that is necessary to relieve the difficulty. In the severer cases, continuous wet dressings and hospitalization may be required. Burow's solution, containing 1 per cent alum and

intractable cases this precipitating factor may have disappeared or become so altered by the passage of time and the development of local perianal changes that it is no longer significant, but it must be remembered that at one time there were factors favorable for the development of an itch in this region. It must also be recognized that the incidence of recurrence in this disease is high following alcohol injections, undercutting operations and other procedures in which a definite cessation of itching and relief from the tendency to scratch have been established, indicating that there are other underlying factors than the mere scratch-itch syndrome.

A wide range of factors may be responsible for the development of anal pruritus, and in long-standing intractable cases many factors may be involved in a single patient. Stokes¹ has divided into five groups the factors that should be considered in establishing the etiology of a given case of anal pruritus. These are considered below.

Physiologic Factors

The anorectal region contains a sweat apparatus called the apocrine system, which, similar to the axillary, submammary and periumbilical areas, is a part of the sexual glandular system and has, among others, two important characteristics: the sweat contains protein and excess carbohydrate and is more alkaline than ordinary sweat, and the apocrine sweat glands are peculiarly responsive to emotion, particularly sexual tension. This area, with its high-protein and high-carbohydrate content and alkalinity, is thus an ideal medium for the introduction of fungous infections and secondary invaders.

The physiologic state of the gastrointestinal tract itself may be important. It is not unusual to find that a stubborn constipation or diarrhea — owing to an atonic or spastic bowel — aggravates an anal pruritus.

There has been considerable discussion on the effect of intestinal flora on this condition. We have had little experience with studies of the intestinal flora and, in general, have not been impressed with the importance of this factor. We have had no experience with the use of autogenous vaccines. It has seemed sufficient to establish a normal bowel function, and adequate treatment of an irritable colon has been of value in the treatment of many stubborn cases.

It has been noted that many soaps are irritating in this condition. In patients who have a deficient amount of fat in their normal skin secretion, the excessive use of soap often causes local irritation. The sodium salts of saturated fatty acids are relatively irritating, and the sulfite in certain toilet tissues has been reported as a frequent source of irritation.

Excessive carbohydrate intake not only predisposes to an increased alkalinity of the part affected

but also causes an increased hydration of the skin. Excessive fruit juices may have the same effect. Alcohol, as a peripheral dilator, may be significant.

Infective Factors

The role of fungous infections in anal pruritus has received considerable attention.² Terrell and Shaw³ reported an incidence as high as 60 per cent in cultures taken from the perianal area. In the few patients in our series on whom careful bacteriologic studies were made, the incidence of fungous infections was not high. Pyogenic flora, with occasional hemolytic streptococci, were the usual findings. Stokes¹ has pointed out that a variety of organisms may be associated with the disease, many of which, generally considered nonpathogenic, seem to become pathogenic for the patient concerned.

Allergic Factors

An allergic background has been encountered in a few of our patients with anal pruritus. Frequently, however, the exact relation of the anal itching is difficult to evaluate. Certain patients exhibit an apparent susceptibility to certain food allergens. A contact sensitivity to mercury, found in many of the surgical lubricants, and the absorption of phenolphthalein, frequently used in laxatives, may cause local sensitization and pruritus.

Psychogenic Factors

The importance of psychogenic mechanisms should never be overlooked in anal pruritus. Nearly every patient with an intractable anal itch presents a history of episodes causing tension. The relation of fatigue and worry can be noted in every patient and financial upsets, family maladjustments and frustrations are frequently observed. A patient with a long-standing anal pruritus usually develops a fixation on the anal area to such an extent that any upsetting influence to his existence is reflected by an anal itch, and his entire attention may be directed either to the actual itching or to the anticipation of the next episode of difficulty. This fixation may become so serious that the patient is on the verge of complete mental collapse. Such patients are desperate for lack of rest, are completely incapacitated and require immediate and serious attention.

Stokes mentions the anal erotic type of anal pruritus, which we have encountered in a small number of patients, usually young men. Sexual problems may enter into many of these cases.

Anal pruritus was an extremely rare disease in the Armed Forces as compared with its incidence among civilians. In my experience, which was largely confined to combat infantrymen but included many thousands of hospital admissions, I recall only one patient presenting an intractable anal pruritus; he was obviously maladjusted, and his one desire was to be transferred out of the

combat zone. The majority of these men, experienced infantrymen, had the highest morale and were too busy and occupied most of the time to develop an anal fixation and spend their time worrying and itching and scratching. It must be remembered that these men were frequently without baths or clean clothes for days at a time and were in a hot, humid climate.

Mechanical Factors

Nearly every case of anal pruritus is precipitated by some local mechanical factor. If this itching begins when certain other favorable factors exist and relief is not obtained, the condition may become intractable.

Minor trauma to this area is not unusual. The act of defecation may cause an abrasion or a fissure. The effects of instrumentation, rubbing or scratching may begin an itch. Hemorrhoids may be responsible, but probably less frequently than has been believed. Large skin tags, however, by rubbing together, causing congestion and interfering with mechanical cleanliness of the area, often seem to be important.

A contracted anal ring, a condition referred to in the literature as pectenosis, is a frequent factor. Infected or inflamed crypts are rarely involved, in our experience.

TREATMENT

A general physical examination, including an anoscopic and proctoscopic examination of the lower bowel, should be done in all cases. Routine blood counts and a urine examination should be carried out. In the majority of cases, after examination, the cause will be obvious, and the treatment apparent. In many, however, further laboratory and roentgenologic studies will be required and possibly the help of the dermatologist, internist, gastroenterologist or psychiatrist. It is to be noted that the original or precipitating factor in the long-standing case of anal pruritus may have disappeared and, from the standpoint of therapy, may not be particularly significant.

For constitutional treatment, the most important requirements are adequate rest, relaxation and relief from tension. Hospitalization and temporary out-patient adequate sedation may be necessary in severe cases. A small amount of a combination of a tincture of belladonna and luminal, particularly when there is an associated spastic colon, is a helpful sedative. Chloral hydrate ensures a good night's sleep. A normal bowel function should be established as early as possible, and the intake of carbohydrate, excess roughage and alcohol should probably be reduced.

Excessive sweating, which may be troublesome, is the only indication for radiation therapy, since in our experience cases in which such therapy was used routinely nearly all recurred after a period of six

to eight months of temporary relief, and it was found that they were invariably much more difficult to control. We have observed cases in which cancer developed in the anal area from the excessive use of radiation therapy. At the present time it is rarely used.

The presence of seborrhea, psoriasis, eczema, contact dermatitis and certain other strictly dermatologic conditions should not be overlooked. Special studies, particularly for food allergies, may be necessary in certain stubborn cases.

In considering local therapy, we are in entire agreement with Stokes that too much attention has been given to this phase of the management of the patient with anal pruritus. Most patients with long-standing intractable anal pruritus have had one or more series of radiation treatments, undercutting operations or alcohol injections, hemorrhoidectomy, cryptectomy, rectal dilatation or some other surgical procedure. They present a scarred anal ring and perianal area that has obviously been made worse by such treatment. Many of these patients had never been instructed to keep themselves clean and stop scratching.

Several years ago, while doing an alcohol injection on a patient with anal pruritus, I found a visitor very much interested in the procedure and in the disease. She was a missionary who had been in charge of a hospital in India for many years and had never seen a native with an anal pruritus of the type described in the literature, the explanation, in her opinion, being the fact that the Indians had never known modern toilet tissue and merely washed themselves frequently. Certainly, adequate local hygiene is the basis of any local therapy for anal pruritus. That this is not the only factor, however, was borne out by my experience in the Army referred to above.

Our patients are routinely advised to wash themselves often with cotton moistened in warm water and to eliminate toilet tissue and soap. They are instructed never to touch themselves with their fingers or any object other than cotton. The ensuing dryness and cleanliness and the avoidance of trauma will indefinitely control many of the mild cases of anal pruritus.

Among the local medications, potassium permanganate, in a strength of 65 mg to 1 liter of hot water, is used almost routinely. Patients with a mild pruritus are instructed to sit in a basin of this solution for fifteen to twenty minutes at a time as often as is necessary to control the itching. The usual cause of failure in the use of potassium permanganate has been that the solution has not been employed for a sufficient period. The application of a 1 per cent solution of phenol in calamine lotion may be all that is necessary to relieve the difficulty. In the severer cases, continuous wet dressings and hospitalization may be required. Burow's solution, containing 1 per cent alum and

3 per cent lead acetate, is mild and helpful. Castellani carbolfuchsin paint — containing carbolfuchsin, phenol, boric acid and water, with or without resorcinol — is satisfactory in many cases, at first it should be diluted 1:2 and 1:3. Extremes of heat or cold may give prompt relief in certain acute situations.

In general, nonirritating, bland solutions are used and greases and ointments avoided. When lubrication is required, castor oil or olive oil may be helpful but should be employed sparingly. Frequently, following the continued use of potassium permanganate soaks, the skin tends to become dried out and mildly irritated. If actual fissures develop, ammoniated mercury ointment or a 2 per cent silver nitrate solution may aid healing. The coal tar preparations are at times indicated.

There are definite indications for surgery in these patients, but as our experience with this condition has increased, surgery has been used less and less. Surgery should be directed toward the removal of sources of infection and the correction of obvious local disease. Infected crypts should be drained, a contracted anal canal should be corrected and large edematous skin tags that interfere with local hygiene of the area should be removed. The routine removal of hemorrhoids relieves few patients. Anal fissures should be excised, and fistulas should be removed.

At a certain period in our experience with this condition, a number of the more serious cases were treated with alcohol injections. Both the techniques described by Stone⁴ and Buie⁵ were used. Temporary relief was obtained in all patients. Permanent relief was apparently obtained in a high percentage treated with the Buie technic, particularly when sufficient alcohol had been given to cause an actual slough, with complete destruction of the skin. The excessive scarring resulting from many of these procedures, however, was certainly not desirable. We have had a limited experience with the injection of local anesthetic-in-oil preparations. Temporary relief of anal pruritus has also been obtained following the injection of large quantities of both saline solution and distilled water. We have had no experience with the local injection of oxygen, with any of the tattooing procedures or with the Ball undercutting operation or any of its various modifications.

It has seemed to us that one factor common to all these different procedures has not been sufficiently emphasized, namely, local anesthesia to the

affected part. This gives definite relief from the scratch-itch syndrome and enables the patient to rest. The only real justification in these radical procedures is this common denominator. They should be reserved for the severe cases in which rapid complete rest and relaxation are imperative. It is our firm belief, however, that the incidence of recurrence will remain high if complete reliance is placed on these surgical procedures, and adequate attention is not given to the various factors that may be in the background and to the restoration of the perianal skin to its normal tone and consistency.

* * *

When patients with anal pruritus are first seen they should be given a brief but intelligent discussion of the subject. In this way, the patients themselves are often able to suggest etiologic factors that obviate expensive study and consultation. The patients must understand that they are faced with what may be a chronic condition. They must learn to treat themselves and to forestall recurrence of the anal itching. It should be pointed out to them that rest, relaxation and freedom from nervous tension are essential for permanent relief and that the object of local treatment is to eliminate infection and to restore an irritated, infected area to its normal state. When surgery is indicated, the definite limitations of the surgical procedure and its object should be pointed out. In many patients who present themselves with a long-standing anal pruritus for which they have been promised a cure following surgery, no attention has been given to any of the other factors that may have been responsible for the disease. The physician who regards the patient with an intractable anal pruritus as a neurotic and gives him no attention deserves little sympathy, the latter has a real disease that can be serious and disabling, but with a reasonable appreciation of the responsible factors and an intelligent approach to the treatment of the patient and the local condition, satisfactory results for this distressing condition can be achieved.

MEDICAL PROGRESS

ABDOMINAL SURGERY (Concluded)

ARTHUR W ALLEN, M D *

BOSTON

APPENDICITIS

Keyes and Cook⁴⁷ discuss the differential diagnosis in acute appendicitis in the presence of diarrhea. This combination occurs rarely but often enough to be kept in mind, especially in children or when the inflamed appendix is adjacent to the rectal wall. In appendicitis the pain is not relieved by the passage of a stool or flatus with or without enemas, whereas temporary complete relief is always thus obtained in gastroenteritis. Vomiting is more frequent and more prolonged in gastroenteritis, and the white-cell count is usually higher in appendicitis. Tenderness in the pelvis on rectal examination is diagnostic of appendicitis.

Fifty patients with proved appendiceal peritonitis were treated with massive doses of penicillin by Crile.⁴⁸ Half the cases were considered to be generalized peritonitis, and the others were localized. Eight patients had palpable masses at the time of entry, and 25 had masses during the course of observation. Twenty-three were treated conservatively, 22 had immediate appendectomy, and 5 had exploration only. After experience with smaller doses, Crile concluded that it was necessary to give 100,000 units of penicillin every two hours for two to six days, or until clinical signs had abated, followed by smaller doses for three or four additional days. The average period for the large doses was four days. Crile believed that the patients treated conservatively did better than those operated on immediately. A strict Ochsner regimen was carried out, with continuous gastric suction until normal peristalsis returned. There was a notable lack of ileus in the group. Masses disappeared under the treatment, and none had to be surgically drained, some of the pelvic abscesses, however, may have drained spontaneously through the rectum. Thirty-six per cent of the appendectomy wounds became infected, but were not tender and usually were not serious. There was one death in the group from mesenteric thrombosis. Experimental data are offered in support of the rationale for the large dosage used. This was based on the apparent inhibiting influence of *Escherichia coli* on the effect of penicillin.

It is quite probable that future reports on the use of streptomycin in such cases may be even more

spectacular. It should be borne in mind that Crile's patients had accepted methods of treatment hitherto found useful, in addition to the penicillin. Furthermore, the results in these cases, which occurred in military personnel, are compatible with earlier statistics concerning optimum recoveries for a similar group.

The differential diagnosis of acute appendicitis and acute, nonspecific mesenteric adenitis is ably presented by Aird.⁴⁹ *Tabes mesenterica* is more frequent in children and adolescents but may occur at any age. A history of acute infection — particularly of the throat — preceding the attack is often obtained. The pain is colicky, with relief between spasms. The temperature is usually higher, and there is more associated nausea and vomiting than is generally seen in appendicitis. The localization of the tenderness is above McBurney's point and slightly to the right of the umbilicus, discomfort on palpation extending from this region diagonally toward the left upper quadrant. This distribution of tenderness follows the course of the small-bowel mesentery. Discomfort on rectal examination is absent. The white-cell count is frequently lower than that usually found in appendicitis but may be high, with an increase in polymorphonuclear leukocytes. Aird suggests a virus infection as the etiologic agent, based on negative cultures from biopsied lymph nodes in the acute phase of the disease. He states that spontaneous recovery within forty-eight hours is the rule, a history of repeated attacks is frequent.

Although appendectomy does not appear to affect an acute mesenteric adenitis, it must be borne in mind that the differential diagnosis is not always possible. It is safer to explore many of these patients and remove the appendix than it is to overlook a true appendicitis with bizarre symptomatology and physical findings. Future attacks, if they occur, do not cause the same alarm to the patient, his family or the physician after the appendix has been removed. Furthermore, there is considerable evidence of a reduction in acute abdominal episodes due to mesenteric adenitis after appendectomy.

According to Etherington-Wilson,⁵⁰ 80 per cent of the cases of torsion of the great omentum are diagnosed preoperatively as acute appendicitis. The literature yielded 190 cases of this condition, and the author reports 4 cases of his own. Twisting of the

*Lecturer in surgery, Harvard Medical School, chief, East Surgical Service, Massachusetts General Hospital.

great omentum may be complete or partial, the latter at times being represented by a single strand. The strangulation of the blood supply may also be partial or complete. The torsion may be unipolar, representing the primary or idiopathic type, or bipolar from a secondary fixed point. There were 73 cases of the primary type, which were exclusively intra-abdominal and without known cause. The secondary rotations may be unipolar or bipolar, occurring as a result of omentum fixed within a hernial sac, adhesions or deformity and caused by past or present inflammation. The condition is usually acute but may be subacute or chronic. Men between twenty and fifty years of age are generally affected. A combination of factors is probably responsible. These include abnormal peristalsis, contractions of the abdominal wall and diaphragm, sudden twisting or jerky motions of the body, direct blows on the abdomen, omental disfigurements by tumors, overloading or uneven fat deposits, pedicle formation, scarring, raggedness, adhesions, bipolar attachments and displacement of the omentum during operations for abdominal tumors.

THE STOMACH AND DUODENUM

Ladd et al.⁵¹ report the experience with congenital hypertrophic pyloric stenosis at the Children's Hospital, Boston. From 1915 to 1945 a total of 1145 cases were treated, 588 patients were admitted in the first twenty years covered in this report. There were 35 deaths in this group — a mortality of 5.95 per cent. In the ten-year period from 1935 to 1945, there were 577 cases with 5 deaths — a mortality of 0.89 per cent. There were no deaths in the last 225 cases. The value of preoperative preparation, ether anesthesia and the Robertson gridiron incision is emphasized.

Hobbs and Cohen⁵² collected from the literature 40 cases of gastroduodenal invagination and presented an interesting case report of a sixty-one-year-old woman whose intussusception was due to a submucous lipoma of the stomach. Reduction and sleeve resection resulted in recovery. The authors stated that lipomas constitute about 3 or 4 per cent of all benign tumors of the stomach, and they found only one other report of invagination due to lipoma. Prolapsing mucosa, pedunculated adenomatous polyps, pancreatic rests and leiomyomas appear to be the most frequent etiologic agents.

Moses⁵³ collected 150 cases of diverticulum of the stomach. The symptoms are similar to those of ulcer, and the diagnosis is made by roentgenographic studies. Relief is obtained by excision of the diverticulum. Walters⁵⁴ discusses the subject and adds 3 new case reports of this lesion. He refers to an earlier report of 2 cases from the Mayo Clinic.⁵⁵ Brown and Priestley⁵⁶ cite a case of diverticulum of the stomach associated with acute massive hemorrhage.

The experience with carcinoma of the stomach at the New Haven Hospital is reported by Lawrence and Kay.⁵⁷ They compare two series of cases in the decades from 1920 to 1940 and find that the patients did not report to the hospital earlier in the latter group, however, the resectability had increased, and the operative mortality had decreased. There was a 40 per cent loss owing to obvious inoperability or to the patient's refusal of operation. The lesions in 35.5 per cent of patients explored were not resectable, 8.8 per cent of patients were lost through operative mortality, whereas 9.3 per cent gradually declined and died after leaving the hospital. Of 208 patients admitted, 4.4 per cent were alive and symptom free at the end of five years, and 2 per cent died of other causes. There was a corrected salvage of 21 per cent in the 48 patients undergoing resection.

Reiteration of the importance to the physician and the layman of early diagnosis and radical treatment in cancer of the stomach is warranted. Temporary relief of indigestion by an ulcer regimen and advertised remedies is misleading. Every effort should be made to study these patients properly and to institute correct therapy before the tumor is out of bounds. The most frequent fault is the conservative treatment of middle-aged people for an ulcerative lesion of short duration. The relief of symptoms often seen without disappearance of the ulcer results in the false impression that benign ulcer is the cause, and the chance for cure is lost.

Waugh and Fahlund⁵⁸ report 77 cases of total gastrectomy by the abdominal approach from the Mayo Clinic, with an over-all mortality of 44.2 per cent. The mortality rate dropped to 3.2 per cent in 44 patients operated on between 1940 and 1943 but rose again to 20 per cent during 1943. The authors point out the value of experience in this field of surgery as being the chief factor in reducing the operative risk. Over 50 per cent of their patients who survived lived for more than two years.

Smithwick⁵⁹ reported 10 cases of total gastrectomy, with emphasis on an aseptic anastomosis between the esophagus and the jejunum by means of a special clamp he has devised. One patient was alive and well ten and a half, and another five and a half years after operation. There was no operative mortality in the 7 cases in which the aseptic technique was used.

Lahey,⁶⁰ in a discussion of Smithwick's paper, reviewed the experience with total gastrectomy by the abdominal approach in his clinic. In 92 cases 2 patients survived for over five years after this procedure for lymphosarcoma of the stomach. The mortality rate has been reduced materially in recent years.

Kelly⁶¹ reported the case of a patient who was alive and well seven and a half years after total resection for carcinoma of the stomach. The patient developed primary anemia after some years and

as restored to health by the institution of liver and iron therapy

Malignant lesions of the duodenum are discussed by Dixon et al,⁶² who found a total of 49 cases, exclusive of those arising in the papilla of Vater, in the records of the Mayo Clinic. Operation was performed in 45 cases, and 4 were revealed at autopsy. There were carcinomas in 44 cases, sarcomas in 2, a lymphangioendothelioma in 1 and associated carcinoma of the stomach in 2. Obstruction was the prominent feature in 38 patients, whereas anemia was the prevailing finding in 6. The mortality from exploration and palliative procedures was 22 per cent. Segmental resection was performed in 4 cases, and local excision in 1, with 10 deaths, and in the 4 patients subjected to radical resection, there was death in 1. One patient was alive and well six years after operation. Interestingly enough, another patient lived for seven years after gastroenterostomy before succumbing to the disease.

In a collective report on duodenal ulcer in England and Wales, Wood⁶³ states that there were 43,000 fatal cases of this lesion in the decade before World War II and that 200,000 new cases occur each year in those countries. He mentions the increase in ulcer during the London Blitz and emphasizes the mental and psychic elements in the etiology. He agrees that the problem is primarily medical, surgery being reserved for complications. Although extensive resection is regarded as the best method of treatment in properly selected cases, he has observed reasonably favorable results in a limited number of cases treated by the method of Somervell.

Somervell⁶⁴ describes his technic of interrupting five sixths of the blood supply to the stomach, in addition to posterior gastroenterostomy, as a method of treating duodenal ulcer. He compares 400 patients so treated with 300 who had been subjected to subtotal gastrectomy. He states that gastric acidity remained lowered for five years by his procedure, with only 1 case of anastomotic ulcer. There were 7 cases of stomal ulcer in the gastrectomized patients. This is similar to the early attempts to cure hyperthyroidism by progressive interruption of the blood supply to the gland. It must be borne in mind that, in interruption of the blood vessels to the stomach, the influence of the altered nerve supply may also have a bearing on the results.

Dragstedt⁶⁵ has revived interest in vagus resection for the cure of duodenal ulcer. Much enthusiasm is being demonstrated in this approach. The immediate results at the Massachusetts General Hospital in nonobstructing duodenal ulcer are impressive. If this operation, performed transthoracically, proves permanent, it will offer a simple solution to the problem. We are watching with considerable reservation the vagus interruptions below the diaphragm, because of the difficulty of exposure of the nerves

and the limited segments that can be removed by this route.

Stomal obstruction following gastroenterostomy is discussed by Gray and Sharpe,⁶⁶ who stress the two types met—one developing in the first few days and mechanical in origin, and another occurring from the seventh to the tenth postoperative day. If the mechanical arrangement is at fault, it may need operative correction. In the later, functional type jejunostomy for feeding will take care of the situation. Experience and careful technic of operation are regarded as obviating most of these difficulties.

Alesen⁶⁷ has devised an absorbable fenestrated tube made of beeswax, petroleum jelly, powdered elm bark and merthiolate with a melting point of 85°C to be incorporated within the gastroenterostomy stoma. He believes that early obstruction is the most important to overcome and that this framework is sufficient for this purpose. The tube, which disintegrates as the elm bark expands, disappears from the stoma in ninety-six hours.

Usually, early obstruction responds to decompression of the stomach segment by gastric suction through a nasal catheter. The late obstructions are extremely troublesome in my experience, occurring frequently in depleted patients. A proximal jejunostomy tube, whose tip lies in the stomach, has been used with complete satisfaction in over 300 cases. Minor complications have arisen, but none that offset the comfort and safety of the procedure.⁶⁸ No fatal cases have resulted from the use of this method of decompression. In many cases a jejunostomy for feeding is also used, particularly in patients with prolonged obstruction and resultant malnutrition.⁶⁹

Three excellent articles on the feeding of patients in preparation for surgery and during convalescence have appeared. All present variations of mixtures containing skimmed milk, skimmed-milk powder, Amigen, eggs, soy-bean flour, sucrose and salt. Varco⁷⁰ believes that patients who have lost weight should be treated by the addition of 5000 to 6000 calories of this liquid nonresidue mixture daily to the hospital diet. He states that it requires ten to twelve days of preparation for a weight loss of 20 per cent, three weeks for one of 25 to 30 per cent and a month for a loss above 35 per cent. The liquid is kept beside the patient, who is encouraged to take as much as he will. If he cannot take it voluntarily, it is introduced through a nasal tube by gravity. After this preparation, patients appearing in a depleted condition withstood major operations on the stomach or colon much better than those in an earlier series not treated in this manner.

Riegel et al⁷¹ and Lund⁷² have also outlined the nutritional requirements of patients, with particular emphasis on protein. The formulas vary slightly, and the daily caloric values are based on maintenance rather than on the correction of previous

weight loss, as stressed by Varco.⁷⁰ Many variations can be worked out, and some of the mixtures appear to be more palatable than others. The viscosity can be reduced to allow for jejunal feedings by the Murphy drip. Vitamins and liver extract can be added.

Fewer problems are involved in patients who can take nutritional mixtures or properly prepared food either voluntarily or by gastric or jejunostomy tube than in those who require intravenous feeding as the main source of nourishment. So far, there seems to be a limit to the amount of carbohydrate and Amigen that can satisfactorily be used by this route. Further purification of the constituents employed for intravenous feedings and a better understanding of their management are needed.

Custer and his associates⁷¹ have studied the problem of the so-called "dumping stomach" following subtotal gastrectomy. They believe that the symptoms of weakness, generalized and unpleasant sensation of warmth throughout the body, a cold diaphoresis of the face (particularly of the forehead) and cardiac palpitation after eating are due to the rapid emptying of the stomach into the jejunum. They found that 5.6 per cent of 500 patients studied complained of one or more of these symptoms, some of them obtained relief by lying down after eating, and many were finally relieved. This ultimate relief is explained on the theory that the jejunum becomes adjusted to the early deposit of food, and it is recommended that patients be instructed to experiment with the following measures for relief: to lie down after eating, to take 0.024 gm ($\frac{3}{8}$ gr) of ephedrine with two or three soda crackers before meals, 30 cc of cream or 45 cc of olive oil before meals, six small meals daily, a dry diet, and 10 drops of dilute hydrochloric acid half an hour before eating.

All who have seen many patients after gastrectomy are at a loss to explain the variation in their state of well-being. We found that 87 per cent of patients with duodenal ulcer were well after subtotal gastrectomy.⁷⁴ Women were likelier to complain of weight loss and discomfort after eating than men. I am not convinced that rapid emptying of the stomach remnant is the whole explanation of these symptoms. To be sure, postprandial discomfort is a more frequent complaint after total gastrectomy than after subtotal, but many of these patients eat well and without distress and a few are hungry. There seems to be a reflex in some cases that may be based on changes in the autonomic nervous system. I am sure that many of the rapidly emptying stomach segments create no symptoms.

Perman,⁷⁵ of Stockholm, informs me that if these manifestations are severe and the patient is invalidated by them, relief can be obtained by disconnection of the gastrojejunostomy and the establishment of a gastroduodenostomy. This appears to be a logical solution, since the food then passes over a more nearly normal route. The Billroth I procedure

can rarely be done satisfactorily at the time of adequate subtotal gastrectomy for duodenal ulcer, but doubtless can be quite easily accomplished at a later date, when the elements of inflammation in the duodenal stump have disappeared.

THE SMALL INTESTINE

A review of the literature by Williams and Walker⁷⁶ has revealed 300 cases of diverticulum of the jejunum. Two case reports of their own are added, one of which had been studied repeatedly over a number of years for pain and fullness in the upper abdomen, with negative findings. Finally, a diverticulum of the jejunum was diagnosed by roentgenograms, and relief of symptoms was obtained following excision of the lesion. The other patient was admitted with an acute abdominal condition and a pelvic mass. On exploration, bilateral ovarian cysts with twisted pedicles were removed, and a perforated diverticulum of the jejunum was excised. Other diverticula were noted in a 50-cm segment of the jejunum, which was successfully resected six weeks later. In both cases, on microscopic examination, the diverticula contained all the normal structures present in the jejunum.

Atwood⁷⁷ observed 37 cases of Meckel's diverticulum in 69,000 admissions to the Truesdale Hospital. He presents an excellent review of the developmental background of the lesion and discusses the causes of small-bowel obstruction associated with it. He gives a case report of intussusception due to invagination of a Meckel's diverticulum.

Two cases of repeated massive hemorrhage, with the passage of bright-red blood by rectum, due to neurofibromas of the ileum, are reported by Baker and Halley.⁷⁸ After excision of these tumors, no intraluminal ulceration was revealed in the specimens. This feature is unusual, and it seems unlikely that such a large amount of blood could have been lost except through an open vessel within the lesion. Similar tumors frequently found within the stomach become umbilicated in the central portion, and these depressions lead to an easily recognized open artery if the specimen is removed during or shortly after excessive bleeding.

Moses⁷⁹ gives an excellent discussion on acute small-bowel obstruction. He stresses the fact that most of these patients are admitted to the hospital in an acutely depleted state and therefore should usually not be subjected to immediate surgery. Careful and intelligent attention to the correction of fluid and electrolyte balance and shock is the first consideration. In patients who cannot be brought out of shock, operation offers no additional hope for cure. Usually, these patients can be made ready for surgery in a period of hours, and preoperative preparation should not be prolonged beyond the optimum period for intervention. Moses reports 118 patients admitted, with 10 deaths, 90 were operated on, with

deaths Of the 14 requiring resection of gangrenous segments, 3 died

Foissie⁸⁰ emphasizes the high incidence of small-bowel obstruction occurring in veterans after recovery from abdominal wounds This late complication is bound to occur frequently after the penetration and repair of the abdominal viscera

Calihan, Kennedy and Blain⁸¹ review the experience with acute intestinal obstruction at Johns Hopkins Hospital for a ten-year period They found that 20 per cent of 204 patients succumbed fifteen-five per cent of the deaths were due to peritonitis The duration of the obstruction was a vital factor in recovery Strangulation, followed by gangrene, and perforation were the primary causes of the fatal peritonitis On the basis of experimental work in the same clinic by Blain and Kennedy,⁸² Calihan et al believe that antibacterial therapy, particularly with penicillin, will materially reduce the mortality in acute small-bowel obstruction Dogs with isolated loops of small intestine treated with penicillin lived twice as long as control animals With penicillin, the strangulated bowel became thickened, so that gangrene and perforation were delayed They believe that their evidence points toward the bacterial theory, rather than toxic elements within the strangulated loop of bowel, as the chief cause of death

Harris⁸³ reports the use of a single-lumen tube with a mercury-weighted balloon for decompression of the small bowel This tube is of smaller outside dimensions than an effective double-lumen tube and yet has a larger lumen He advocates the use of 4 cc of mercury in the balloon and calls attention to the difficulty met in withdrawing this balloon through the pylorus In two cases the mercury was spilled within the bowel without harm to the patient The tube was occasionally allowed to pass intact through the rectum

The members of the resident staff of the Massachusetts General Hospital have preferred this new tube to the Miller-Abbott tube They find it easier to get through the pylorus and that decompression of the obstructed loops of bowel is more quickly accomplished By using the laws of gravity, there has been little trouble in causing the mercury to flow in the right direction within the balloon when the tube needs to be removed Less than 4 cc of mercury is often enough, and this amount is seldom troublesome

Another single-lumen weighted tube has been described by Cantor,⁸⁴ who recommends more and larger fenestrations in the tube The high openings in the tube are designed to pick up secretions from the stomach, as well as at intervals along the intestine It appears that the benefit of the principle of the decompression tube may be lost by this method, since the normal secretions above the obstructed loop contain valuable chemical elements that are absorbed if not removed Also, this tube

prevents the absorption of water, nutritious fluids and electrolytes that can often be administered while the decompression tube is in place

THE COLON

Schlotthauer⁸⁵ calls attention to the familial tendency in diverticulosis of the colon He reports a family of 7 brothers, all of whom were afflicted with this ailment Two sisters in the family did not have diverticulosis Reports in the literature indicate the incidence of this disorder to be from 2 to 5 per cent of the population Certainly, this figure is much too low for persons beyond middle age

Meyer et al⁸⁶ have given a good program for the preparation and aftercare of the patient in colon surgery They cleanse the bowel with cathartics and enemas and then use succinylsulfathiazole (Sulfasuxidine) for several days They take pains to bring about a chemical balance and adequate blood replacement. Spinal anesthesia is preferred Open primary anastomosis after resection of the remaining colon was carried out in 25 patients, with 1 death from embolism Early mobilization is stressed Proximal decompression is omitted Wounds are closed primarily with interrupted wire sutures Patients averaged thirteen days in the hospital after operation

Thomson and Daland⁸⁷ report the use of phthalylsulfathiazole (Sulfathalidine) in the preparation of patients with cancer of the colon and rectum, 1 gm of the drug being given every four hours for five or six days preoperatively The patients were usually well prepared for surgery, and the semisolid state of the fecal matter still in the colon was considered preferable to the more liquid effect of succinylsulfathiazole In spite of the slipping back into the peritoneal cavity of the colostomy in 2 cases, one of which was not recovered for eight hours, there was only 1 death in the series of 49 cases This fatal case occurred following resection of the splenic flexure after a cecostomy decompression for complete obstruction The effect of the phthalylsulfathiazole was thereby thwarted, and death resulted from peritonitis Sulfadiazine was given intravenously after operation Primary anastomosis was done in all lesions of the colon

Segmental resection in the left colon with primary aseptic anastomosis in 50 cases is reported by Waugh and Custer⁸⁸ There were 2 deaths in the group The Rankin three-bladed clamp was employed as the basis of the anastomosis The hospital stay in this group was greatly reduced, the safety of the procedure demonstrated, and the short morbidity emphasized when compared with a large group of patients treated by exteriorization operations

Another report of primary anastomosis following colon resection is presented by McMillan⁸⁹ In 27 consecutive cases in which operation was performed, there was 1 death from pulmonary complications

He stresses the use of two rows of interrupted non-absorbable sutures in the anastomosis. The patients averaged eighteen days in the hospital.

It is interesting to those who have always used primary anastomosis following resections of the colon to find such a general interest in this procedure. Obstructive resections and other exteriorization methods have been satisfactory to many surgeons. It is creditable that the shorter period of disability from primary anastomosis has not increased the risk in the hands of surgeons using the various aids in preparation, anesthesia, suture material, operative technic and aftercare now at their disposal. I believe that delayed wound closure is a safeguard in addition to those mentioned above.

Olsson⁹⁰ emphasizes the need for careful examination of patients with cancer of the colon. The percentage of multiple lesions, in his opinion, is much higher than is usually believed. In one year, he found between 50 and 60 cases during examination of 700 or 800 patients. In 5 cases multiple lesions were found.

In 42 out of 220 patients with cancer of the colon and rectum, Sugarbaker⁹¹ found involvement of other structures that could be removed. He reports a resectability rate of 78 per cent in a group of patients coming from a district where advanced disease, with weight loss and so forth, was the rule. Resectable extensions were found in the abdominal wall, uterus, urinary bladder, prostate, vagina, iliac vessels, ureter and femoral nerve. The vagina was involved more frequently than the prostate, probably owing to the thick fascial covering of the latter. Patients with other structures involved by continuity had symptoms of cancer of the bowel an average of fifteen months as against thirteen months in those without these extensions. The mortality rate in 72 patients in whom no other structures were involved was 9 per cent, whereas in the other group 19 per cent died, 19 patients with involvement to neighboring structures were alive two to five years after operation.

Young and Cole⁹² present some interesting experimental evidence that intraperitoneal succinylsulfathiazole and phthalylsulfathiazole may be useful when the peritoneal cavity is contaminated by fecal matter. These drugs were absorbed more quickly and created less adhesions than other sulfonamides. No toxic reaction was evident in dogs receiving 1 gm per kilogram of body weight. The proved effect on *Esch coli* by the oral use of succinylsulfathiazole and phthalylsulfathiazole makes it logical to try these drugs intraperitoneally when indications arise. Young and Cole have treated a small group of patients with 0.1 gm per kilogram of body weight without harm and suggest that larger intraperitoneal doses are probably safe.

It is interesting in this connection that Poth et al⁹³ have found that penicillin inhibits the action of phthalylsulfathiazole and does not seem to affect the

properties of succinylsulfathiazole, no explanation being available for this antagonism.

An excellent discussion on the management of the permanent colostomy is presented by Miles and his associates⁹⁴. The daily colostomy enema or wash out seemed to be favored by the majority. A few preferred to let Nature take its course. Some believed that patients could train their colostomes to function at a certain hour each day. There was little support of the use of bags or cups. Miles seemed to give the most logical advice for these patients. He recommends a daily wash out of the colon with 750 cc (1½ pints) of plain water at 80°F. He stresses the fact that hot water creates inertia of the muscular coat of the colon. Enemas should be introduced with the patient lying down, so that the muscles will be relaxed. He recommends finger dilation of the colostomy opening daily for a month, once a fortnight for two months and, finally, once a month for six months. After this, there is little tendency for contraction to take place. He uses a simple belt for support and disapproves of bags and cups, which produce prolapse, edema and bleeding of the mucous membrane.

CASE 33051

PRESENTATION OF CASE

A sixty-six-year-old furniture crater entered the hospital because of exertional dyspnea.

Six years before entry, the patient had had an attack of pneumonia requiring four weeks' hospitalization, during which he received sulfadiazine, and rest at home for eight weeks. During this period he had gained 20 pounds in weight, which he had maintained. On resuming work he felt "better than ever before" but noted some exertional dyspnea and night sweats. He also had an occasional nonproductive cough and two or three paroxysms of coughing daily. Two months before entry, the patient saw a local physician because of continuing dyspnea and was referred to this hospital. During the summer before entry, he lost 8 pounds, which was not unusual for him during hot weather.

Physical examination showed a well preserved man in no discomfort. The only positive findings were scattered rales over the left lung base posteriorly.

The temperature was 99°F, the pulse 70, and the respirations 18. The blood pressure was 170 systolic, 90 diastolic.

Examination of the blood disclosed a hemoglobin of 14.0 gm and a white-cell count of 15,500, with 83 per cent neutrophils, 5 per cent lymphocytes, 8 per cent monocytes and 3 per cent eosinophils.

The nonprotein nitrogen was 25 mg per 100 cc. The urine was normal.

An x-ray film of the chest showed the left hilus to be considerably increased in size and moderately elevated. Irregular linear bands of increased density extended outward into the upper middle and lower lung fields. The heart shadow was displaced to the left, and there was an inspiratory shift of the mediastinum to the left. The diaphragm moved fairly well. Within the density in the left hilus was a 2-cm sharp line, suggesting a fluid level in a small cavity.

Bronchoscopy of the right bronchial tree was negative. The left main bronchus was normal, down to the upper-lobe orifice. Close to this orifice, which appeared slightly narrowed, there was narrowing of the left main and left lower-lobe bronchi, with some fixation and a slightly nodular appearance. Several biopsies from this area were reported as showing chronic inflammation.

On the eighth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR EDWARD D. CHURCHILL. We are to discuss the case of a patient with a serious illness that led to operation. As the record stands, we must accept the facts that the symptomatology was of long duration and that all symptoms dated back to the episode of pneumonia six years before entry. It is always important to find out just what brings a patient to the doctor at the time that he summons the courage to make the trip. Nothing in the record, however, gives any lead to new symptoms or to an increase or change in old symptoms that might have led this patient to consult a physician two months prior to admission. The presenting symptom is recorded as "continued dyspnea." Even the significant fact of whether he had or had not raised blood is lacking.

DR TRACY B. MALLORY. Can you answer that, Dr Sweet?

DR RICHARD H SWEET I am impressed by the difference between the story obtained in the hospital and that obtained in my office. I have the recollection that the patient had had recent symptoms of cough and occasional staining with blood, but I may be wrong.

DR CHURCHILL Is this fact, not being given in the history, admissible as evidence?

DR MALLORY Yes, I think you had better use all the information available.

DR CHURCHILL You will admit blood spitting?

DR SWEET My recollection is that the patient had had occasional recent spitting of blood, which was intermittent.

DR CHURCHILL Not every day, and occurring within the previous few months?

DR SWEET That was my impression.

DR CHURCHILL Consequently, there was a change that brought about a visit to a physician two months before admission. There is also no note of whether the sputum was examined in the hospital. We then focus our attention on a differential diagnosis between chronic infection and neoplasm of the lung.

May we see the x-ray films?

DR JAMES R LINGLEY This is the enlarged left hilus that was described, with what looks like a fluid level in the central portion, outlining a cavity about 2 cm in size. In addition, there are linear bands of density extending upward into the upper, middle and lower lung fields. The bands are also visible in this lateral view, extending backward to the base of the upper lobe and forward into the lower lobe. The heart is slightly displaced to the left side, and fluoroscopically a note was made that there was a mediastinal shift to that side on respiration.

DR CHURCHILL Where is the cavity on the lateral film?

DR LINGLEY The fluid level is not adequately demonstrated in the lateral view. I suspect that the cavity was posterior to the hilus, but I cannot be sure.

DR CHURCHILL Was the cavity peripheral?

DR LINGLEY I cannot be sure.

DR CHURCHILL Can you localize this process in the lateral film — whether it was in the upper or the lower lobe, or both?

DR LINGLEY I think that it involved both, but it was more marked in the base of the upper lobe.

DR CHURCHILL Do you think that this is a cavity far posteriorly?

DR LINGLEY That location in general.

DR CHURCHILL In this case the differential diagnosis lies, as I have said, between chronic infection with or without an acute exacerbation and a bronchiogenic carcinoma. I am not satisfied with the history as presented in the record, because there is nothing to suggest that a new entity, such as carcinoma, had come into the picture. If we admit

the recent appearance of blood spitting, an increase in exertional dyspnea, some feeling of fatigue, some stiffness of the joints or a dozen other symptoms that might have taken this man to a physician two months before entry, I think that we are tipping the scale toward bronchiogenic neoplasm. I must raise one other question. In discussing another patient, Dr Sweet recently stressed the point that an abscess cavity in the lung of purely inflammatory origin is usually peripheral, whereas in neoplasm it may be central. If we apply that yardstick to Dr Lingley's interpretation that the cavity was centrally rather than peripherally placed, it favors carcinoma. This would have been a good case in which to try out examination of the sputum for tumor cells, but we are proceeding without sputum examination. The bronchoscopic findings were quite significant so far as narrowing and fixation of the bronchus were concerned. Such fixation is a sign that is associated with carcinoma rather than an inflammatory condition. There was no recent history of a bad cold or an attack of grippe, which might have exacerbated an old pneumonitis. A lung abscess appearing six years after pneumonia is unusual, and lacking further evidence I consider the scales weighed toward bronchiogenic carcinoma. I am willing to proceed with Dr Sweet, if that was his diagnosis, with a thoracotomy incision for inspection and probable removal of the lung.

DR MALLORY Dr Sweet, do you want to tell the operative findings?

DR SWEET Perhaps Dr Benedict would like to describe the bronchoscopy.

DR EDWARD B BENEDICT It is all given in the record. I did say "partial fixation," however — not complete.

DR SWEET I have been trying to obtain my office record because my impression was so different, and I regret that I did not review the history of the hospital record before it was presented. But, as I have said, my impression was that a definite change in the form of the cough or some expectoration with an occasional streaking of blood caused the patient to consult a physician.

I was not certain what the diagnosis was ahead of time. Dr Benedict and I have often labored over cases of this type, and in quite an appreciable number we have been forced to perform an exploratory thoracotomy. As Dr Churchill suggested, that is what we did. Before operation I was not certain whether the cavity was central or peripheral. My impression was that it was central, but it actually was peripheral. We made a thoracotomy incision and discovered that the most adherent portion of the lung was in the region of the dorsal division of the lower lobe, the adhesions were of the character that we have learned to associate with chronic infection. They were so dense that one could not develop a plane of cleavage. The lung had to be separated with a knife, but I did not believe that

here was a special indication for entering the extra-pleural fascial plane. In separating that portion of the lung from the chest wall, however, I opened into the cavity, which presented the usual appearance of a chronic inflammatory cavity. It did not look like a lung abscess or carcinoma, but in the region of the hilus there was an indurated area that I thought was carcinoma. The structures about the hilus were almost typical of carcinoma — so much so that when I began to dissect about the hilus, I said, "This is probably an inoperable case, even if I can do a pneumonectomy, it is incurable." There were firm, hard lymph nodes that were beyond the limit of my ability to reach. I completed the pneumonectomy, and I was sure the lung and lymph nodes would show malignant disease. The perihilar tissue — not only the nodes, but also the areolar tissue — was adherent. It was difficult to develop the vessels. There was a good deal of contraction of structures, and the phrenic nerve was pulled over.

CLINICAL DIAGNOSIS

Bronchiogenic carcinoma of lung?

DR CHURCHILL'S DIAGNOSIS

Bronchiogenic carcinoma of lung

ANATOMICAL DIAGNOSES

Chronic pulmonary tuberculosis

Tuberculosis of bronchial lymph nodes

PATHOLOGICAL DISCUSSION

DR SWEET This case was different from the cases of tuberculosis in which we have operated, the majority of which have shown a free hilus, which could be dissected with relative ease. I should like to point out that in the field of thoracic surgery there is an analogy with abdominal surgery in cases of this sort. Often, I have been confronted, as other surgeons have, with the difficulty in differentiating an inflammatory mass in the cecum or sigmoid and a carcinoma. I remember a case that was discussed here of a patient on whom I had operated, performing a right colectomy in the belief that I was dealing with carcinoma. Dr Castleman came over to see it and could not tell what it was. It turned out to be an appendiceal abscess. Dr Allen remarked that he had had that experience himself. In other words, on the operating table it is difficult to differentiate some cases of chronic infection or tuberculosis of the colon and carcinoma, and the same thing is true of the lung.

DR MALLORY The lung we received showed extensive tuberculosis with a large cavity at the apex of the lower lobe. The lymph nodes at the hilus were also involved with firm, dense, fibro-caseous tuberculosis.

CASE 33052

PRESENTATION OF CASE

First admission A forty-eight-year-old machinist was admitted to the hospital because of a productive cough.

At the age of twenty-five the patient had had "double pneumonia" and typhoid fever, and he had suffered from influenza during the 1918 epidemic. At the age of thirty-one a rib resection had been performed because of a left-sided empyema. The patient stated that during the succeeding two weeks he could "blow smoke through a hole in his back", this closed during the next two and a half months, however, and he fared well except for a chronic dry cough and occasional colds that settled in the "left bronchial tubes." The recent cough had begun nine months previously, when he had had a severe cold progressing to pneumonia with a temperature of 101°F and a cough productive of "heavy pus" without blood or chest pain. During the two weeks of confining illness, he lost 17 pounds. Following this he continued to have a cough productive of one or two tablespoonfuls of yellow-white, sometimes foul-smelling, sputum, especially in the morning. He also complained of persistent weakness and general malaise. Six months before entry the feet became chilled and the patient was again confined to bed for three days with chills and fever. A similar episode occurred two months later. The patient had never coughed up blood since the original empyema.

There was no family or other history of exposure to tuberculosis. The patient had done considerable welding and had been exposed to zinc oxide.

Physical examination in the Out Patient Department three months before admission revealed that the left leaf of the diaphragm was elevated, with limited excursion, there were a soft inspiratory wheeze over the left base posteriorly and occasional crackling inspiratory rales over the same area with questionable dullness and diminished breath sounds. X-ray examination revealed a cavity filled with air and fluid in the posterior aspect of the left chest at the level of the hilus, where there was a band of increased density reaching to the diaphragm. The left lower lobe appeared to be somewhat decreased in size. In the lower portion of the cavity there was a mottled area of increased density that had the appearance of old lipiodol. There was a partial resection of the ninth rib on the left.

Three months later the patient was admitted to the hospital. The x-ray and physical findings were essentially unchanged. A tuberculin test was negative in a concentration of 1:10,000. Examination of the blood showed a red-cell count of 4,260,000 and a white-cell count 8550, with 40 per cent neutrophils, 49 per cent lymphocytes, 8 per cent monocytes, 1 per cent eosinophils and 2 per cent basophils. Repeated x-ray series were negative.

A right lower lobectomy was performed, and

pathological examination was reported as showing lung abscess with chronic pneumonitis and pleuritis. Following operation there was persistent drainage of 30 to 40 cc of foul pus from the wound without fever and despite sulfadiazine administration. X-ray examination revealed adequate expansion of the remaining lung, with no mediastinal shift. There were only a small amount of fluid and a few streaks of atelectasis at the base of the lower lobe. Lipiodol injection revealed a fistulous communication with the left lower bronchus with no intervening cavity. The patient was discharged to be followed in the Out Patient Department.

Second admission (four months later) Follow-up study in the Out Patient Department revealed the tract to have gradually closed and after two months extended only into the chest wall. A repeat x-ray examination disclosed essentially the same findings as previously with some thickening of the pleura along the left chest laterally and posteriorly without definite effusion. During the following month the patient had fever and malaise with increased drainage, the fistula reached the pleural space, but no pocket of pus was evident. Two weeks later an abscess developed in the old operative scar. It was incised and drained and found to extend to the bone. Culture revealed a few colonies of *Staphylococcus aureus*.

Two weeks later the patient was readmitted to the hospital because of a new abscess. Incision and drainage of the new area revealed an abundant growth of *Staph aureus* on culture. The patient was discharged on the seventh day.

Third admission (five weeks later) The drained areas failed to heal, and more furuncles continued to develop so that there were six different areas, most of which drained thin pus with cheesy particles that on smear and culture were negative for tubercle bacilli and showed moderate growth of *Staph aureus*. The patient was readmitted for biopsy and open drainage of the entire area.

Physical examination showed no changes in the five months since the lobectomy, except for the evident weight loss of 30 pounds and the draining sinuses.

X-ray studies with lipiodol injections of three fistulas were unsatisfactory but revealed no definite interconnection. The white-cell count was 25,000, and the red-cell count was 4,100,000, with a hemoglobin of 65 per cent. Examination of the urine showed only rare, short granular casts and 8 to 10 white cells per high-power field in the sediment.

Drainage of the area was accomplished surgically with a rib resection and secondary closure. Pathological examination of the tissue was reported as showing acute and chronic inflammation, with granulation tissue and a foreign-body, giant-cell reaction. The last x-ray film showed the seventh, eighth and ninth ribs resected posteriorly. The tenth rib was fractured, with a mottled area of decalcification.

Final admission (two months later) The patient was readmitted because of a bronchocutaneous fistula that had developed two weeks previously. He experienced considerable pain and cough during the week before admission and raised small amounts of yellow-white sputum without blood. He complained of profuse night sweats, with a temperature of 101 to 102°F, but there were no chills.

Physical examination was essentially unchanged aside from the emaciated appearance and a new bronchocutaneous fistula.

Examination of the blood revealed a red-cell count of 3,800,000, with a hemoglobin of 80 per cent, and a white-cell count of 21,700. Repeated examinations of the urine were negative. An x-ray film disclosed a small amount of periosteal proliferation of the eighth and ninth ribs and little change in the thickened pleura. Subsequent re-examinations showed a small amount of new-bone formation about the ends of the resected ribs. In addition, there was a moderately large air-containing cavity in the posterior portion of the left lung field with no evidence of undrained fluid.

In the hospital the patient continued to have pain in the ribs on the left, a spiking temperature up to 102.5°F, with profuse night sweats and continued thick yellow-green purulent drainage of the fistulas. On one occasion he coughed up "three mouthfuls" of blood. He was given testosterone and repeated blood transfusions. The white-cell count in two weeks fell to 15,000, and the red-cell count rose to 5,130,000 with a hemoglobin of 85 per cent.

Three weeks after admission an x-ray report mentioned a definite collection of fluid posteriorly in the left chest, probably at the level of the fifth rib. During the following week a new rib resection was performed.

DIFFERENTIAL DIAGNOSIS

DR F DENNETTE ADAMS The history at the time of the first admission was characteristic of bronchiectasis. At first glance it seems reasonable to suppose that this patient's trouble started at the age of thirty-one with an attack of lobar pneumonia. Empyema appearing spontaneously is rare, and the spitting of blood was probably due to pneumonia rather than to empyema. The bronchopleural fistula doubtless resulted from rupture of a small subpleural abscess. Following recovery, one might postulate that the process in the lung did not entirely clear, the patient was presumably left with some residual damage, such as an area of bronchiectasis at the site of the original pneumonia. One can assume that, as so often happens in these cases, complicating episodes following the acute upper respiratory infection consisted of repeated bouts of acute bronchopulmonary disease in the affected area. The physical signs in the thorax — dullness, elevation of the diaphragm, diminished breath sounds, and rales — are consistent with this explanation.

indicating probable pleural thickening and contraction, localized pulmonary fibrosis and bronchiectasis. The localized wheeze is confusing and cannot be accounted for. Usually indicative of partial obstruction of a bronchus, this sign is highly suggestive of emphysema. Because of the presence of trapped air, with partial bronchial obstruction, however, one expects expansion, not contraction, of the affected area of the lung, the findings should have been not dullness but hyper-resonance and prolonged expiratory rales. Examination of the lungs provided no evidence of cavitation, probably because of the deep location of the cavity.

May we see the first x-ray films?

DR LAURENCE L. ROBBINS: These are the first films taken and show the thickened pleura and an air-containing cavity, which appears to be in a dorsal division of the left lower lobe. There is a collapse—that is, a decrease in the size of the lobe—because the lobe is too small generally, but the greater portion of the trouble appears to be in the dorsal division.

DR ADAMS: Could the shadow said to have been the appearance of lipiodol be caused by any other foreign substance? We have no record of lipiodol injection.

DR ROBBINS: It could be calcification, I suppose, but it looks much more like lipiodol.

DR ADAMS: Attention must be directed to certain factors in the record that throw considerable doubt on the explanation of the illness just postulated. In the first place the patient had no trouble from the age of thirty-one until nine months before admission, when he was forty-seven and when all the acute episodes occurred, it is hard to believe that with either bronchiectasis or abscess he could have gone sixteen years with no symptoms and then have been repeatedly in trouble. Secondly, at that time, the patient lost 17 pounds within two weeks—a much greater weight loss than is usual in acute infection superimposed on bronchiectasis or in pneumonia. Thirdly, x-ray examination showed an abscess cavity that was thin walled and, although productive of sputum, gave a smaller daily output than is usual in a postpneumonic abscess. These facts force me to the conclusion that the episode nine months before entry was new and not related to the empyema and the postulated lobar pneumonia. The character of the cavity and the amount of sputum are not inconsistent with coccidioidomycosis although typically one sees even less tissue reaction around the cavity than that in this case. This disease can be dismissed on the grounds of probability, since we have no record that the patient ever resided in an endemic area.

The laboratory tests give no clues. The result of the blood Hinton test is not reported.

DR. TRACY B. MALLORY: We can assume that it was negative.

DR ADAMS: All one can say up to the time of the first operation is that the patient had an abscess of undetermined origin, probably of neither tuberculous nor postpneumonic origin.

Following operation the patient was in continuous trouble. At no time was he entirely free of draining sinuses, and after a few months, new abscesses and draining sinuses continued to appear in spite of repeated surgical measures. X-ray study disclosed evidence of bone destruction, and eventually a bronchocutaneous fistula developed. Meanwhile, the patient went downhill, with severe weight loss, increasing fever and marked elevation of the white-cell count. A further indication of his poor condition is the need for transfusions and testosterone, the latter given presumably in an effort to restore nitrogen balance. Sulfonamides and penicillin were doubtless given and proved ineffectual.

DR MALLORY: The patient received sulfonamides repeatedly. This case occurred before the era of streptomycin. Penicillin was given only toward the end of the last admission.

DR ROBBINS: This film, taken shortly after lobectomy, shows more pleural reaction than one would expect. This next film simply confirms the presence of the bronchocutaneous fistula, the lipiodol enters the left main bronchus and then goes into the portion of the upper lobe. This film was taken approximately five months after the post-operative episode, and there is an increase in the pleural reaction. The changes in the periosteum on the inner surface of the ribs, which usually go with secondary infiltration with empyema, begin to be visible. The resected ribs are again seen, and this film shows beginning new-bone formation, but it does not seem to be so marked as usual. These films show the collection of fluid posteriorly that was mentioned at the time of the final admission. I think that there is some change in this vertebra, but the films were not taken for that purpose.

DR ADAMS: What about the fractured rib?

DR ROBBINS: It does not seem to have regenerated so rapidly as they often do, and in all these films there are questionable areas of bone destruction.

DR ADAMS: Fracture because of destruction?

DR ROBBINS: No, probably the result of operative procedures.

DR ADAMS: We are confronted, then, with a patient who, nine months following an acute pulmonary infection of some kind, was found to have a lung abscess. The clinical picture did not conform to that usually seen in postpneumonic abscess. Following lobectomy, instead of getting well, as was anticipated, the patient continued to be in difficulty. The systemic reaction was severe, multiple abscesses and fistulas and eventually a bronchial fistula developed. The possibility of tuberculosis seems to be ruled out by the x-ray films and the pathological findings, as well as by the negative cultures. I should be more confident if a guinea-pig

test had also been performed and reported negative.

A chronic suppurative process due to *Staph aureus* is suggested by the repeated isolation of that organism from the pus, but I doubt whether it could be held responsible for the large number of fistulas and, in a chronic case such as this, for the severe systemic reaction. Once drainage had been established, that should have been sufficient. More help might also have been expected from the sulfonamides.

A foreign body, perhaps a sponge, is a possibility, but again one would expect a single and persistent draining sinus — not multiple sinuses.

One not infrequent disease of the lung is manifested by the appearance of multiple stubborn sinuses, and I believe this to be the cause of this patient's illness. Although typically it causes multiple small abscesses of the lung, I suppose it could produce a large one, an explanation is provided for the unusual character of the abscess — that is, for its failure to conform to the pattern of postpneumonic cavitation. This disease also readily accounts for the extreme systemic reaction, loss of weight, emaciation and high fever. In my opinion the only likely diagnosis in this case is actinomycosis.

A PHYSICIAN: Did the yellow pus have any relation to the actinomycosis? Were the sulfur granules cultured?

DR MALLORY: That is a question that often comes up. In all probability the laboratory was never asked to look for actinomycosis. The specimens were examined in the routine bacteriologic laboratory and repeatedly examined in the surgical bacteriology laboratory, and in neither were actinomycetes found, I cannot say how specifically they were looked for, however.

DR BEVERLY TOWERY: We recently had a patient in the Baker Memorial Hospital with a chronic infection of the chest wall, after two weeks' study we were convinced that she had actinomycosis, and yet

it took a week of careful search to find the sulfur granules. I have seen three cases within the year — one with recurring liver abscesses, the case that I just mentioned and another that simulated chronic gall-bladder disease — in which the patients had actinomycosis. It is essential to realize the protean nature of this infection so that its presence may be suspected more frequently and the organisms may be looked for in fresh material.

CLINICAL DIAGNOSIS

Actinomycosis of lung

DR ADAMS'S DIAGNOSIS

Actinomycosis of lung, with abscess formation and bronchocutaneous fistula

ANATOMICAL DIAGNOSIS

Actinomycosis of lung

PATHOLOGICAL DISCUSSION

DR MALLORY: At the final operation some tissue was removed in which we were able histologically to demonstrate actinomycosis. We went back over all the previous specimens, including those from the original lobectomy, and in none were we able to find organisms. The organisms are often few and far between. There is a good deal of chance in picking the right location from which to take a section. It is reasonable to assume that the history from the beginning can be explained on the basis of actinomycotic infection.

DR DONALD S. KING: Are cavities with a fluid level usually seen?

DR MALLORY: We expect multiple small cavities instead of a single cavity.

DR ADAMS: I tried to find out about that point from the literature in the short time that I had to prepare this case. Most articles merely refer to cavitation.

POSTGRADUATE LECTURE COURSE

THE three-month Postgraduate Lecture Course given last winter and spring proved to be so popular that, in a somewhat abbreviated form, it will be repeated this year. The program has been arranged by a subcommittee of the Subcommittee on Postgraduate Education of the Committee on Postwar Planning of the Massachusetts Medical Society, in co-operation with the Massachusetts Department of Public Health. The lectures will be given on Mondays — from 5.30 to 7.00 and from 7.30 to 9.00 — and on Wednesdays — from 3.00 to 6.00 — beginning on March 3 and ending on April 23. A buffet supper will be served on Mondays between 7.00 and 7.30. As formerly, all exercises will be held at Sanders Theater, Harvard University, Cambridge.

A tentative outline of the program appears elsewhere in this issue of the *Journal*. All the topics are of general interest, and the chairmen have been so wisely selected that adequate and timely discussions are guaranteed. Of special interest is the topic for the first day — "The Medical Aspects of Atomic Warfare." The session will be presided over by Dr. Stafford Warren, professor of radiology at the University of Rochester School of Medicine, and Dr. Shields Warren, pathologist at the New England Deaconess Hospital, Boston. The former, while in the Army, served as medical director of the Manhattan Project, and the latter, while in the Navy, was director of medical research at the Bikini Test. They undoubtedly know more about the medical aspects of atomic warfare than any other persons in the world, and the program, which will include motion pictures of the Bikini Test, should provide three hours of intensely interesting instruction and entertainment.

The course is primarily intended for the practicing physicians of Massachusetts and the surrounding states, but hospital residents and interns and medical students are cordially invited to attend. All those who plan to be present are required to register, but no charge will be made other than one for those who participate in the suppers on Mondays. A copy of the final program will be forwarded to all licensed physicians in Massachusetts, and a return postal card will be enclosed requesting information concerning attendance at the first lecture, the majority of lectures and the buffet suppers. To aid the subcommittee, all postal cards should be promptly returned. Those who wish to register immediately should do so by writing to the Postgraduate Lecture Course Committee, Massachusetts Medical Society, 8 Fenway, Boston.

NATIONAL HEART WEEK

Just as modern warfare demands the active co-operation of a large segment of the civilian population, so the war against disease can no longer be left entirely to a relatively small professional body. In girding itself for a vigorous offensive against man's greatest killer the American Heart Association has undertaken a fundamental reorganization involving extensive lay participation. It is seeking not merely

to broaden its membership base but also actually to take nonmedical persons into its executive bodies up to 50 per cent of the membership of each. This means that the lay members may have an equal voice with the physicians in determining the general policies of the association. Such an arrangement cannot fail to be a stimulating one for both groups. At the same time the Scientific Council, open only to members of the American Heart Association who have made significant contributions to knowledge of cardiovascular disease, will maintain the high scientific standards of the association. Another feature of the reorganization is closer integration with the local heart associations, such as the New England Heart Association, including joint membership. Recognizing that rheumatic fever stands out as one of the most urgent unsolved medical problems of the day, the American Heart Association has accepted the responsibility of incorporating the American Council of Rheumatic Fever within its structure. The objectives of the council are to aid and guide local communities in the organization of programs designed to attack the rheumatic-fever problem, to prepare and distribute criteria for the diagnosis of rheumatic fever and rheumatic heart disease, together with recommendations for treatment and convalescent care, to educate groups of physicians, nurses, social workers, teachers and so forth and to sponsor research.

The American Heart Association will carry on the publication of the *American Heart Journal*, *Modern Concepts of Cardiovascular Disease* and special pamphlets. It will provide slides, pictures, exhibits, models and so forth for instruction and will co-ordinate programs of postgraduate education throughout the country among medical schools, hospitals and county societies. It will assist in the development and establishment of standards for accurate diagnosis, clinics, facilities for acute and convalescent hospital care, nursing care, occupational therapy, vocational guidance and medical social service, periodic health examinations and vital statistics. It will carry health education to the public, and it will aid the cardiac patient in securing employment. Finally, it will accept responsibility for stimulating, guiding, co-ordinating, sponsoring and financing research along statistical, clinical, labora-

tory and epidemiologic lines. The 1947 budget for carrying out this program is \$561,000, including \$275,000 for research.

The inauguration of the public-education program has been appropriately observed by the proclamation of National Heart Week — February 9 to 15. During this period every medium of information — the press, radio, magazines, motion pictures and special events — will be used to drive home the message that the control of heart disease is the most vital health problem confronting the public today. The campaign will be purely educational, no public drive for funds being contemplated at this time. Physicians will be well advised to be prepared to answer questions from their lay friends and patients regarding the objectives of the American Heart Association.

MASSACHUSETTS MEDICAL SOCIETY EXECUTIVE COMMITTEE OF THE COUNCIL

The Executive Committee of the Council, in regular session on January 8, 1947, approved the following recommendations submitted by the Committee on Membership:

That the following named fellows, applying for retirement and with all dues paid and in good standing, be allowed to retire under the provision of Chapter I, Section 5, of the by-laws:

Champion, Merrill E. (Suffolk), 42 Anderson Street, Boston
Cook, Philip H. (Worcester), 19 Somerset Street, Worcester
Cummin, John W. (Suffolk), 416 Marlboro Street, Boston
Hamblet, Mary L. (Essex South), 120 Federal Street, Salem
Hosley, Walter A. (Middlesex South), Salem Road, R F D, Danvers
Lakeman, Mary R. (Essex South), 108 Federal Street, Salem
MacDonald, William C. (Middlesex South), 21 Mountain Avenue, Newtonville
Thayer, Hartley W. (Middlesex South), 355 Walnut Street, Newtonville
Tucker, S. Chase (Essex South), 379 Lowell Street, Peabody

That the following named fellows, applying for resignation and with all dues paid and in good standing, be allowed to resign under the provisions of Chapter I, Section 7, of the by-laws:

Burke, Edward W. (Middlesex South), 55 Bradford Boulevard, Tuckahoe, New York
Pratt, Henry N. (Norfolk), 444 East 68th Street, New York 21, New York
Spira, Bertram (Barnstable), 626 S. Alvarado Street, Los Angeles, California
Zielinski, John B. (Bristol South), 781 Carroll Street, Brooklyn, New York

That the following named fellows, applying for resignation from the Massachusetts Medical Society but in arrears of dues, shall have these dues owed the Massachusetts Medical Society remitted under the provisions of Chapter I, Section 6, of the by-laws and shall then be allowed to resign under the provisions of Chapter I, Section 7, of the by-laws

Marchand, Jean (Essex South), 210 Lafayette Street, Salem

Shpiner, Leonard (Middlesex South), 509 Arcade Building, Kankakee, Illinois

Snow, Robert (Middlesex East), 1146 Gilmer Drive, Salt Lake City, Utah

That the following named fellow be allowed to change his legal residence from one district society to another, without change of district membership, under the provisions of Chapter III, Section 3, of the by-laws

Heusner, A Price (Suffolk), 647 Pleasant Street, East Weymouth

MICHAEL A. TIGHE, *Secretary*

EATH

HOWARD — Pérez B. Howard, M.D., of Newtonville, died January 18. He was in his seventy-first year. Dr. Howard received his degree from Harvard Medical School in 1902. He was a fellow of the American Medical Association.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

REVIEW OF COMMUNICABLE DISEASES IN 1946

More than 100,000 cases of communicable disease were reported in Massachusetts during 1946, exceeding the 1945 total by 20,000 cases. The increase was due mostly to the record-breaking number of measles cases that occurred in the spring, complemented by increases in German measles, chicken pox and dog bite. No serious outbreaks of devastating diseases took place during the year, however, and on the whole the experience with communicable disease can be considered as extremely satisfactory.

The Commonwealth was fortunate to escape with only 377 cases of poliomyelitis during an epidemic year that proved to be the greatest the Nation has experienced since 1916, when a total of 1927 cases, with 452 deaths, occurred in Massachusetts. The most alarming development of the past year was the marked increase in diphtheria, which began in July and culminated in a total of 441 cases, more than doubling the incidence for any year since 1937. This strongly indicates the immediate need of intensifying immunization efforts, especially in Boston, Gloucester, Lowell, Lynn, New Bedford, Somerville, Taunton and Worcester, where the disease has been frequent.

The prevalences of other communicable diseases did not show impressive changes during the year. Slight to moderate increases were reported in Salmonella infections, trichinosis, pulmonary tuberculosis and typhoid fever. On the other hand,

sharp decreases occurred in the incidences of scarlet fever, mumps and lobar pneumonia. A decline also was reported in bacillary dysentery, meningococcal meningitis and whooping cough.

Lobar pneumonia broke last year's all-time low to reach the lowest incidence in the history of the Commonwealth, with a total of 1484 cases, compared with 2137 in 1945. No cases of smallpox, leprosy or human rabies were reported.

Following is a list of the communicable-disease totals reported in Massachusetts during 1945 and 1946, together with the seven-year medians

DISEASE	1946	1945	SEVEN YEAR MEDIAN
Actinomycosis	-	2	4
Anterior poliomyelitis	379	527	182
Anthrax	2	4	5
Chancroid	19	20	2
Chicken pox	11506	10401	11808
Diphtheria	441	194	154
Dog bite	11705	10585	10585

CONSULTATION CLINICS FOR CRIPPLED CHILDREN IN MASSACHUSETTS UNDER THE PROVISIONS OF THE SOCIAL SECURITY ACT

CLINIC	DATE	CLINIC CONSULTANT
Salem	February 3	Paul W. Hugenberger
Haverhill	February 5	William T. Green
Lowell	February 7	Albert H. Brewster
Greenfield	February 10	Charles L. Sturdevant
Gardner (Worcester subclinic)	February 11	John W. O'Meara
Brockton	February 13	George W. Van Gorder
Springfield	February 18	Garry deN. Hough, Jr.
Pittsfield	February 19	Frank A. Slowick
Worcester	February 21	John W. O'Meara
Fall River	February 24	David S. Grace
Hyannis	February 27	Paul L. Norton

Physicians referring new patients to clinics should get in touch with the district health officer to make appointments.

MISCELLANY

NOTE

The following appointments to the teaching staff of Harvard Medical School were recently announced: Donald Robert Wilson, of Quebec, Canada (B A Oxford University, England, 1937, M D, C M University of Alberta 1931-35), research fellow in medicine, Jacques Antoine Carloti, of Paris, France (M D University of Paris 1940), research fellow in medicine, Wade Volwiler, of Athens, Ohio (A B Oberlin College 1939, M D Harvard University 1943), assistant in medicine, Louis Anthony Sieracki, of Norwood (S B University of Indiana 1927, M D University of Indiana 1929), instructor in pediatrics, Bertram Silverstone, of Norfolk, Virginia (A B Columbia University 1937, M D Harvard University 1941), assistant in surgery, Frederic Crosby Bartter, of Boston (A B Harvard University 1935, M D Harvard University 1940), research fellow in medicine, Thomas Lanier DeLorme, of Randolph (S B Howard College, Alabama, 1939, M D New York University 1943), research fellow in neurology, Gardner Cowles Quarton, of Cedar Rapids, Iowa (S B Harvard University 1940, M D Harvard University 1944), assistant in neurology, Gustave Derouaux, of Liège, Belgium (M D University of Liège 1938), research fellow in physical chemistry, Constance Elaine Field, of London, England (M R C S, L R C P, B M, B S London 1934, M D London 1937, M R C P 1941), research fellow in pediatrics, Theodore Dunham, Jr., of Pasadena, California (A B Harvard University 1921, M D Cornell University 1925, A M Princeton University 1926, Ph D Princeton University 1927), Henry E Warren Fellow in Surgery, Martin Bernard Williamson, of Las Vegas, New Mexico (S B Brooklyn College 1938, A M University of Missouri 1940, Ph D University of Missouri 1943), instructor in ophthalmic research, Sidney Bennett Luna, of Waterbury, Connecticut (S B Middlebury College, 1938, M D Harvard University 1943), assistant in surgery, Ralph Henderson Kellogg, of Saratoga Springs, New York (A B University of Rochester 1940, M D University of Rochester 1943), teaching fellow in physiology, Somers Hayes Sturgis, of Cambridge (A B Harvard University 1927, M D Harvard University 1931), assistant in gynecology, Arthur Stanwood Pier, Jr., of Milton (A B Harvard University 1935, M D Harvard University 1939), assistant in medicine, Beverly Todd Towery, of Bowling Green, Kentucky (S B Western State Teachers College, 1936, M D Vanderbilt University 1940), research fellow in medicine, and John Bruton Scanbury of Mendota, Illinois (A B Duke University 1935, M D Harvard University 1939), research fellow in pharmacology.

The appointment of Paul Hathaway Keyes, of Long Island, New York (D D S University of Pennsylvania 1941, A B University of Rochester 1945, M S University of Rochester 1947), as research fellow in dental medicine, was also announced recently.

CORRESPONDENCE

TRYPTOPHANE AND BLOOD SUGAR LEVELS

To the Editor: As an incident to the experimental ingestion of crystalline *D*-L-tryptophane, it was observed that on ingestion of this essential amino acid, there was, for the persons concerned, a slight but consistent drop in the blood sugar level. Before beginning ingestions on a large scale in an attempt to decrease the caries rate, a small group of young adults volunteered to undergo an experiment to test the blood sugar drop. A dose of tryptophane varying from 0.14 to 0.32 gm., being adjusted to body weight, was ingested by these subjects on four successive days. Then, after a day's rest, the same dose of tryptophane was ingested on four more successive days. The material was taken midway between breakfast and lunch, in crystalline powder form, with as much water as desired. Previous ingestions in gelatin capsules had proved less effective in changing the salivary amylase. All blood samples were taken after a five-hour fast, and the last dose of tryptophane was administered two hours prior to drawing the second samples.

The changes in fasting blood sugar levels following these ingestions are listed below and appear to be significant.

SUBJECT	BLOOD SUGAR	
	BEFORE TRYPTOPHANE	AFTER TRYPTOPHANE
	mg./100 cc.	mg./100 cc.
R C	91	71
G M	75	67
P H	87	89
N T	113	63
L W	87	71
B V	96	64
S T	106	88
N B	101	66
O F	101	67

Among the nine subjects, only one failed to show a decrease in the blood sugar level, and in this instance the level increased from 87 to 89 mg per 100 cc. For the other eight, the average fasting blood sugar was 96 mg (range, 75 to 113 mg) per 100 cc., and that after the tryptophane was 70 mg (range, 63 to 88 mg). This average drop of 26 mg may be of interest in diabetes and possibly in hypoglycemia. In control subjects, from whom blood samples were obtained at the same time as those from the test subjects, there was an average gain in the blood sugar level of 3 mg per 100 cc.

BOOK REVIEWS

Pulmonary Edema and Inflammation. An analysis of processes involved in the formation and removal of pulmonary transudates and exudates. By Cecil K. Drinker, M.D., D.Sc. 84, chb, 106 pp., with 27 illustrations. Cambridge Harvard University Press, 1945. \$2.50.

This monograph is divided into five chapters. The first, a discussion of the anatomy of the lungs as related to the problem of transudation, includes a great deal of information that is of clinical significance — notably, a reminder that the lung capillary endothelium depends for its oxygen on air reaching it rather than on arterial blood and that exudates or transudates in this area must largely be removed through the bottleneck of the lymphatic ducts.

The second chapter discusses the balance of forces that regulate the movement of fluids through the walls of capillaries. A contrast is made between the capillary situation within the lungs and elsewhere in the body, and evidence is presented that the lung is a relatively ineffective organ for ridding itself of excessive transudation, besides anatomical peculiarities, it suffers the handicap of contending against a variable degree of negative pressure within the thorax that acts toward drawing fluid from the pulmonary blood stream.

The third and fourth chapters discuss the treatment of pulmonary edema. There appear to be two appropriate lines of attack: the combating of anoxia and resistance to the tendency of the negative pressure normally present within the chest to increase the flow of water from the lung capillaries. For the former the proper use of oxygen appears clearly indicated, for the latter, no particularly good method is at present available.

The final chapter is concerned with artificial respiration. The author believes that too little attention has been paid to the possibly harmful effect on the lungs of methods usually employed, and he predicts future modifications that will be valuable.

This book contains much more than an original discussion of applied physiology. It is prepared by a talented author who is also an artistic teacher, each chapter is readable, demonstrates on almost every page both scholarship and the writer's familiarity with every stone of the structure to which he has built his views. On the whole, the work does serve high praise, it is not only valuable for reference but also a delightful model for those interested in the art of medical writing.

Pharmacy Fundamental principles and practices, pharmaceutical preparations, biologicals Editor-in-chief, Rufus Lyman, M.D. 4th, cloth, 540 pp., with 197 illustrations Philadelphia J B Lippincott Company, 1945 \$8 00

Lyman and his group of twenty-two collaborators have used an up-to-date authoritative treatise covering the field of pharmacy in a comprehensive manner. The book represents a new trend in textbook construction in pharmacy and has been designed as a teaching textbook and a reference for the practicing pharmacist as a working tool. The authors are specialists in their various fields. The work is divided into three parts. The first part deals with the fundamental principles of the basic sciences as applied to pharmaceutical processes, the second covers the field of pharmaceutical preparations, with emphasis on the processes involved in manufacture, and the third discusses products of biologic origin (the vitamins, hormones and endocrine preparations). The text is well written and printed in two columns with good type on good paper. The book is recommended for medical libraries and should prove valuable as a reference source for all public libraries.

Way of an Investigator A scientist's experiences in medical research By Walter B Cannon, M.D. 8th, cloth, 229 pp. New York W W Norton and Company, Incorporated, 1945 00

The late Dr. Cannon, in this delightful semiautobiography, based on more than forty years of his life spent in the Harvard Medical School, expounds the philosophy of the scientific investigator. He discusses the qualifications of the ideal scientific worker, the necessity of perseverance and stamina, the intuition and accident play in discovery and the problems that arise from the possible errors and misjudgments that are bound to occur in research. Professor Cannon tells of his early home and college life, his travels abroad, his war experiences, his vacations and his years as professor of physiology. The text is written in an easy, interesting style, and this book is worthy of a place in all libraries, medical, scientific in general, and in all private medical collections.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return or the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Master-of-Paris Technique in the Treatment of Fractures and Other Injuries By Lieutenant Colonel T B Quigley, Medical Corps, Army of the United States, instructor in surgery (on leave of absence), Harvard Medical School, and junior associate in surgery (on leave of absence), Peter Bent Brigham Hospital, Boston. 8th, cloth, 107 pp., with 103 illustrations. New York The Macmillan Company, 1945 \$3 50

This manual considers only the mechanical application with one method of treatment of traumatic injuries and only brief mention of the common indications for each cast is made. The diagnosis, evaluation, pathology and prognosis of trauma are not considered. The majority of casts used in ordinary practice are described.

Hematology By Willis M. Fowler, M.D., professor of internal medicine, University of Iowa. With a chapter by Elmer L. Degowin, M.D., assistant professor of internal medicine, University of Iowa. 8th, cloth, 409 pp., with 110 illustrations. New York Paul B Hoeber, Incorporated, 1945 \$8 00

This new textbook on hematology, which was developed by the author from his lecture notes covering the period of the last twelve years, was written primarily for the medical student and the general practitioner, not being designed to serve as a general reference work for those specializing in hematology. The author maintains the viewpoint that hematology is a part of internal medicine rather than a specialty in itself and presents the subject in this light, stressing the clinical and therapeutic aspects of the various diseases. The book is well printed on good paper, with a good type, but is rather heavy for its size.

Clinical Atlas of Blood Diseases By A Piney, M.D., M.R.C.P. physician, St. Mary's Hospital for Women and Children, London, and Stanley Wyard, M.D., F.R.C.P., physician, Royal Cancer Hospital, and Princess Beatrice Hospital, London. Sixth edition. 8th, cloth, 137 pp., with 48 illustrations. Philadelphia The Blakiston Company, 1945 \$5 00

The value of this small atlas is demonstrated by the need of six editions during a period of fifteen years. The book is primarily an atlas, but condensed descriptions of blood conditions accompany the plates.

Amputation Prosthesis Anatomic and physiologic considerations, with principles of alignment and fitting designed for the surgeon and limb manufacturer By Atha Thomas, M.D., associate professor of surgery (orthopedics) University of Colorado School of Medicine, and Chester C Haddan, president, Association of Limb Manufacturers of America. 8th, cloth, 350 pp., with 207 illustrations. Philadelphia J B Lippincott Company, 1945 \$8 00

In this monograph, written jointly by a surgeon and a manufacturer of artificial limbs, the problems of the patient, the surgeon and the appliance maker are discussed on common ground and emphasis is placed on the most satisfactory end results for the patient. The importance of anatomic and physiologic considerations in doing an amputation is stressed in relation to established principles of alignment and fitting. The book is designed as a practical guide for the proper use of prosthetic appliances. This unusual book should be in all medical libraries.

Structure and Function of the Human Body By Ralph N. Baillif, Ph.D., assistant professor of anatomy, Louisiana State University School of Medicine, New Orleans, and Donald L. Kimmel, Ph.D., associate professor of anatomy, Temple University School of Medicine, Philadelphia. 8th, cloth, 328 pp., with 158 illustrations. Philadelphia J. B. Lippincott Company, 1945 \$3 00

The objective of this new manual is to provide a carefully organized text emphasizing the relation of structure and function. The manual, which is written primarily for students, emphasizes the unity of structure and function. The material is well organized and well printed, with a good type, and should prove valuable to all those who have need of such a manual. A special glossary is appended to the text.

Analyze Yourself Enabling anyone to become deeply psychoanalyzed without a personal analyst By E. Pickworth Farrow, M.A., D.Sc. With a foreword by the late Professor Sigmund Freud, M.D., LL.D. New York International Universities Press, 1945 \$2 00

This small book contains a full and detailed account of how to follow a practical method of psychoanalysis of one's own mind. The author used the method on himself and relates his own experiences in recapturing his memory extending over a period of years.

An Introduction to Physical Anthropology By M. F. Ashley Montagu, B.S., Ph.D., associate professor of anatomy, Hahnemann Medical College and Hospital, Philadelphia, and visiting lecturer, Department of Sociology, Harvard University. 8th, cloth, 325 pp., with 25 illustrations. Springfield, Illinois Charles C Thomas, 1945 \$4 00

This manual has been written for the general reader and the student, and it is hoped that it will prove of value to biologists, physicians and psychologists. The author has endeavored to present the fundamental facts and problems necessary for the understanding of man. He discusses in order the primates as a zoological group, the origin and evolution of the primates and of man, the criteria and mechanism of ethnic group differentiation, the divisions and ethnic groups of man, the relation between body, mind and culture, heredity and the influence that the environment has on man. An appendix comprises a practical synopsis of methods of measurement in physical anthropology. In addition to lists of references for further reading appended to each chapter, a general bibliography concludes the volume. The text is easy to read, and the book is printed with a good large type, on good paper. This introduction should prove valuable to all those desiring a short text on the subject.

NOTICES

ANNOUNCEMENTS

Dr Archie A Abrams calls attention to the omission of his office address and telephone number from the current telephone directory. His office is at 1093 Beacon Street, Brookline, and the telephone number is ASPinwall 8951

Dr Volta R Hall announces the opening of his office for the practice of psychiatry at 372 Marlborough Street, Boston

Dr Merrill Moore has returned from military service and announces the opening of his office at 433 Marlborough Street, Boston. His telephone number is COMMONwealth 4216

Dr Bernard J Niemiro, of 207 Elm Street, Holyoke, announces that in the future his practice will be limited to proctology

Dr Robert R Shapiro announces the removal of his office for the practice of general surgery and of surgery of the sympathetic nervous system from 319 Longwood Avenue to 31 Bay State Road, Boston

JOSEPH H PRATT
DIAGNOSTIC HOSPITAL

Bennet Street, Boston

Lecture Hall, 9-10 a m

MEDICAL CONFERENCE PROGRAM

Wednesday, February 5 — The Use of Isopropyl-amine-ethanol in the Management of Bronchial Asthma Dr Maurice S Segal

Friday, February 7 — Diseases of the Veins in Older Patients Dr Edward A Edwards

Wednesday, February 12 — Incomplete and Complete Lacerations of the Perineum Their surgical management Dr Louis E Phaneuf

Friday, February 14 — Clinicopathological Conference Drs Chester S Keefer and H E MacMahon

Wednesday, February 19 — Pediatric Clinicopathological Conference Drs James M Baty and H E MacMahon

Friday, February 21 — The Mechanism of Hemoglobinuria in Thermal Burns Dr Thomas Hale Ham

Wednesday, February 26 — The Use of Streptomycin in Tuberculosis Dr Lowrey F Davenport

Friday, February 28 — Intracranial Aneurysms Dr William H Sweet

On Tuesday and Thursday mornings, Dr S J Thannhauser will give medical clinics on hospital cases. On Saturday mornings, clinics will be given by Dr William Dameshek. Medical rounds are conducted each weekday by members of the staff from 12 00 to 1 00 in the Lecture Hall. All exercises are open to the medical profession

NEW ENGLAND DERMATOLOGICAL SOCIETY

The regular meeting of the New England Dermatological Society will be held in the Skin Out Patient Department of the Massachusetts General Hospital on Wednesday, February 12, at 2 00 p m

TUFTS ALPHA OMEGA ALPHA

The Tufts chapter of the Alpha Omega Alpha will meet in the auditorium of the Beth Israel Hospital, Boston, on Wednesday, February 5, at 8 30 p m. Dr Erich Lindemann will speak on the subject "Some Psychological Problems in Medicine"

APPOINTMENT OF U S P H S MEDICAL OFFICERS

A competitive examination for appointment in the Regular Corps in the grades of assistant surgeon (first lieutenant) and senior assistant surgeon (captain) will be held in the near future

Regular Corps appointments are permanent in nature and provide opportunities to qualified doctors for a life career in one or more of a large number of fields, including research, general hospitals, special hospitals, foreign duty and federal, state and local public-health programs. Assignments are made with all possible consideration of the officer's demonstrated abilities and experience. There is ample opportunity for professional growth and development

All applicants must be at least twenty-one years of age, must be citizens of the United States, must present a diploma of graduation from a recognized medical school and must satisfactorily pass a physical examination performed by Public Health Service officers when directed upon successful completion of the oral and written examination

Applicants for the grade of assistant surgeon must have had at least seven years of educational and professional training or experience exclusive of high school. Applicants for the grade of senior assistant surgeon must have had at least eleven years of educational and professional training or experience exclusive of high school

Application forms may be obtained by writing to the Surgeon General, United States Public Health Service, Washington 25, D C. These should be retained and presented to the Board at the time the applicant appears for the oral examination

Entrance pay for assistant surgeon with dependents is \$3811 a year, and for senior assistant surgeon with dependents is \$4351 a year. Promotions are at regular intervals up to and including the grade of medical director, which corresponds to full colonel at \$8551 a year. Retirement pay at sixty-four is \$4950 a year. Full medical care, including disability retirement at three-fourths pay, is provided. All expenses of official travel are paid by the Government. Thirty days' annual leave with pay is provided

Examinations will be oral and written. The oral examination will be held at several places throughout the country; in the New England area it will start at 10 00 a m on March 4 at the Marine Hospital, 77 Warren Street, Brighton, Boston. The written examination will be held at 9 00 a m on March 27 and 28 at places convenient to the candidates and the Service. National Board grades may be used in place of the written examination for the grade of assistant surgeon

THE ROLE OF THE SURGEON IN THE MANAGEMENT OF PEPTIC ULCER*

OWEN H. WANGENSTEEN, M.D.

MINNEAPOLIS, MINNESOTA

ULCER is a more frequent cause of discomfort and disability than of death—that is, for every patient who dies, a far larger number suffer. Yet approximately 10,000 people die annually in the United States from ulcer and its complications. There has been no suggestion of improvement in this mortality, such as that in appendicitis and bowel obstruction during the past decade.

GENESIS OF ULCER

Autopsy records indicate that evidence of an ulcer or ulcer scar can be found in 2 to 5 per cent of cases. The observations of William Beaumont¹ on Alexis St. Martin and those of Wolf and Wolff² on their subject Tom suggest that gastric erosions occur readily in the stomach. Moreover the observations of Kolouch,³ of this laboratory, on the extenozed gastric or intestinal mucosal patch denote that the progress from a mucosal erosion to a fully developed ulcer can occur during the course of a few hours under the influence of dripping of gastric juice on the patch. The causal antecedent of ulcer—mucosal erosion—probably occurs not infrequently in the lives of persons who never develop an ulcer or suffer ulcer symptoms.

The latitude of difference between a patient who develops a clinical ulcer and one in whom ulcer fails to progress beyond the erosion stage is not measurable. Every person whose stomach responds normally to ingestion of food and other stimuli may be a potential ulcer candidate. Resolving the nature of the ulcer diathesis is not an easy matter.

Ulcer, which often develops spontaneously in man, is decidedly unusual in the ordinary laboratory animals, as both Mann⁴ and Ivy⁵ have been at pains to point out in observations on dogs. The standard laboratory procedure for the production of ulcer in the dog up until recently was the Mann-

Williamson⁶ procedure of moving the duodenal segment, into which bile and pancreatic juice drain, down to the terminal ileum and thus precluding opportunity for neutralization of the acid gastric juice by the alkaline digestive juices. This disarrangement of Nature's plan obviously is distinctly unphysiologic from many points of view, nevertheless, the method has been of value in focusing notice on the great importance of the acid-peptic factor in the genesis of ulcer. This laboratory has for some time been exploring agencies that abet or accelerate the ulcer diathesis. The placement of histamine in beeswax,⁷ from which vehicle the histamine is gradually released, has proved a useful tool in the investigation of items that may favorably influence the ulcer diathesis. By this means alone, ulcer can be produced in most laboratory animals.^{8,9} Moreover, agencies by which the blood supply of the gastric or duodenal mucosa may be altered or impaired appear to favor the development of ulcer. Fractures accompanied by fat embolism may give rise to the spontaneous occurrence of ulcer in man.¹⁰ Fat, injected intravenously into small laboratory animals in small doses, when accompanied by the simultaneous administration of histamine in beeswax, abets and accelerates the development of ulcer. Similarly, anoxic areas produced in the gastric mucosa by the administration of Pitressin or adrenalin favor the development of ulcer.¹⁰ Surprisingly enough nitroglycerin appears to have the same effect.

TREATMENT

The objective of treatment in conditions that threaten life or make patients miserable is to save life, allay symptoms, re-establish normal function and restore the patients to economic usefulness—by the simplest and most effective means. There are essentially three ways of treating an ulcer. In the first the physician—in this instance a psychiatrist or psychosomaticist—endeavors to talk the patient out of his difficulty. This is obviously the simplest form of therapy, but it remains to be proved, despite the present popularity of the method,

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 23, 1946.

This study is based on research supported by grants from the Graduate School, the John and Mary R. Markle Foundation and the Augustus L. Searle Fund for Surgical Research.

how permanent the results of such treatment may be. Secondly, the patient is instructed to eat his way out of his troubles — diet. And thirdly, surgery is invoked with the hope that this expedient will ensure a more lasting cure than that achieved by the two preceding agencies.

As a surgeon, it would be presumptuous of me to attempt to discuss any but the last aspect of this problem.

Indications for Operation

In our clinic, 80 per cent of patients undergoing resection for ulcer have had one or more of the conventional complications of ulcer, including perforation, hemorrhage and obstruction. In our experience, the typical patient accepting resection for ulcer is a man in the middle forties whose symptoms trace back fifteen years. Inasmuch as the patients come largely from the rural areas of Minnesota, the typical patient is a farmer whose work should not be especially conducive to the ulcer diathesis. Moreover, I have been unable to observe in these patients any common behavior pattern, which the routine employment of psychiatric technics might uncover, nor can I see any such uniform physical conformation in ulcer patients as was formerly described under the designation "ulcer habitus."

In this clinic, only 2 patients under twenty years of age have undergone resection for ulcer. One was a boy of fourteen who first suffered a severe hemorrhage from a duodenal ulcer at the age of ten. After an interval of four years, during which many such occurrences threatened his life, a three-quarter resection was undertaken in the presence of massive hemorrhage. More than six years have elapsed, and the boy has grown to manhood. There has been no suggestion of recurrence. The other patient was a nineteen-year-old boy with repeated massive hemorrhages from a duodenal ulcer. He too has remained well.

Approximately a dozen patients in their twenties have been subjected to resection for ulcer. Patients in their thirties are more numerous, and a fairly large number first developed symptoms in the sixth or seventh decade of life. Several patients in their eighties have submitted to resection for ulcer because of compelling indications for operation, or because of long continued dissatisfaction with medical management.

Perforation There can be no disagreement concerning the manner of treatment of perforation. This complication has been an important element in the mortality of ulcer. Yet considerable improvement has resulted from the following methods of dealing with perforated ulcers: the use of unabsorbable (silk) sutures, employing Graham's¹¹ technic of placement of the sutures, lavage of the peritoneal cavity with copious quantities of physiologic saline solution, and the use of chemotherapy. Whereas the general mortality from acute perfora-

tion still hovers around 20 to 25 per cent, in institutions where the above precepts guide the therapy, the mortality is approximately 5 per cent.

Hemorrhage There is room for considerable improvement in the management of hemorrhage attending ulcer. Allen and Benedict¹² were responsible for persuading American surgeons to operate in an attempt to save the lives of patients suffering from massive hemorrhage. The difficulties relative to the problem are many. The decision whether operation should be undertaken is not easily made. Often, too much time is lost by attempts to replace blood loss that is continuing. When a patient has repeatedly been in shock, he is not a good candidate for operation. Physicians and surgeons would do well to consider operating immediately on patients who have a long history of ulcer with previous hemorrhages. The problem may be difficult on other scores. The diagnosis may be in doubt. Gastric cancer, in the experience of our clinic, is not an infrequent cause of sudden massive hemorrhage. And the technical problem in a duodenal ulcer with a large crater may be extremely difficult. The situation usually demands that the duodenum be cut across to find and arrest the source of hemorrhage, then, there remains the extremely difficult task of obtaining a satisfactory closure of the open duodenum — a problem that may be perplexing especially in the large supraduodenal ulcer crater with perforation into the hepatoduodenal ligament. A number of studies suggest that the mortality in patients treated medically for massive hemorrhage is in the neighborhood of 10 to 13 per cent.¹³ Early resort to surgery will spare the lives of many such patients who will otherwise die from exsanguination. In the patient who presents both obstruction and massive hemorrhage, the indication for early surgery is especially imperative.

In this connection, it is probably not out of place to indicate that, in certain cases, the cause of the bleeding remains occult at operation. On the thesis that such bleeding comes usually from a small mucosal erosion that cannot be felt through the gastric wall, I have resected a number of stomachs for massive hemorrhage. Several of these case histories have been reported in detail elsewhere.¹⁴ The situation of fatal bleeding from a single small mucosal erosion in the stomach is well known to pathologists. The condition may be passed over by the surgeon at operation. In cases of massive loss of blood by vomiting, when the surgeon fails to find a likely source for the difficulty, the possibility of a superficial gastric erosion should not be overlooked.

Moreover, bleeding in portal hypertension may also be amenable to correction by gastric resection. It has been taught that the chief source of bleeding is ruptured esophageal varices. Inasmuch as obstruction of the superior vena cava may also give rise to esophageal varices unaccompanied by hemor-

e, may it not be proper to ask whether the ulcer process is due to acid and peptic erosion rather than to hydrostatic rupture? Already, it has been shown that portal hypertension abets the ulcer process.¹⁰ Furthermore, whereas a three-quarter gastric resection uniformly protects against the amine-provoked ulcer in the dog, a 90 per cent resection fails to afford consistent protection against an ulcer in the presence of portal hypertension. Obviously, the intent of gastric resection for hemorrhage in the presence of cirrhosis or thrombophlebitis of the portal or splenic vein, or both, is to prevent death from bleeding and thus to prolong life.

The operation does not do away with portal hypertension. An operation approaching a total gastrectomy will, I believe, protect against hemorrhage. If the bleeding is occurring from gastric or duodenal erosion, the operation should be adequate. If esophageal erosions are responsible, the separation of the esophagus from the portal circulation will relieve the esophageal veins from the increased portal pressure. Moreover, reduction of gastric acidity will diminish the tendency to acid-peptic erosion and the esophageal varices.

Obstruction The most frequent cause of pyloric obstruction is an occult, sealed ulcer crater with extension into the surrounding tissues — that is, the area of induration accompanying a perforating ulcer. A perforated ulcer in juxtaposition to the pylorus suggests about extrinsic duodenal compression and obstruction. The usual location of such an ulcer crater is the posterior wall, with penetration of the pancreas, often, the perforation is into the hepatoduodenal ligament at the superior border of the duodenum. In my experience, the latter circumstance as a cause of obstruction is far more frequent than intrinsic duodenal stenosis. Spasm and mucosal edema, incident to an ulcer near the pylorus, are phenomena that may cause obstructive symptoms. Persistent or recurrent pyloric obstruction generally occurs through Nature's attempt to halt the extension of the ulcer crater. The repair phenomenon of cicatricial contraction is greater in a penetrated ulcer that has extended through all the coats of the gastric or duodenal wall than in an ulcer that has not penetrated through all the layers of the bowel wall. Patients whose obstruction remains refractory to conservative treatment must be operated on.

Pain In approximately 20 per cent of patients subjected to gastric resection in our clinic, the major consideration that prompted performance of the operation was failure to control pain satisfactorily by dietary measures. Occasionally, a patient's own dissatisfaction with the dietary strictures, whether arising from a dislike of the monotony of the diet or from inability to work under its conditions, has constituted the main indication for operation.

DISSATISFACTION WITH MEDICAL CURE

Dr John Fast¹⁴ has just completed a study in our laboratory that strongly suggests the efficacy of the Sippy diet in ulcer management. Five dogs were given 30 mg of histamine in beeswax daily over a forty-day interval. Meanwhile they were fed the Sippy regimen by a gastrostomy tube from 7 a m to 9 p m. At post-mortem examination, ulcer was not observed in a single animal. The only other measure observed that will protect uniformly against the histamine-provoked ulcer is a three-quarter gastric resection.

In most cases dieting for ulcer is not unlike taking insulin for diabetes. It works so long as the medicine is taken. One of the difficulties, however, is that the gastric mucosa is a sympathetic tissue and responds to diverse stimuli of every sort. Almost anything ingested stimulates gastric secretion. Protein-containing foods possess the greatest capacity of uniting with the hydrochloric acid of the gastric juice, and amino acids appear to be more effective in this respect than native proteins. We have found no substrate, however, that, when fed through an indwelling gastric tube, keeps the reaction of the gastric juice in patients with bleeding ulcer consistently above pH 3.5 — the proteolytic end point for pepsin. Arrest of the acid-peptic erosive action of the gastric juice by any agency would be a great boon in the treatment of ulcer, particularly in the management of actively bleeding ulcers.

Nevertheless, dissatisfaction with the dietary management of ulcer is being forcefully expressed. Heuer, Holman and Cooper¹⁵ have reviewed the results of medical and surgical treatment of ulcer at the New York Hospital. They found that approximately 40 per cent of patients have unsatisfactory results from medical treatment. More recently, Krarup¹⁶ reviewed the results of medical treatment of ulcer on Meulengracht's service at the Bispebjerg Hospital in Copenhagen. He observed that the results of treatment were poor in 24 per cent of bleeding and in 43 per cent of nonbleeding ulcers. In patients in whom the duration of ulcer symptoms was longer than a year prior to treatment, the incidence of failure of medical treatment was 32 per cent in bleeding and 45 per cent in nonbleeding ulcers. In patients who had previously undergone one or more medical regimes for ulcer, the incidence of failure was 34 per cent for bleeding and 58 per cent for nonbleeding ulcers. Krarup concluded that in patients whose ulcer distress is of more than a year's duration, and if two medical regimes have been gone through without recovery, the chance of failure of repeated medical treatment is so great that surgical treatment ought to be taken into consideration.

A deterrent, to which careful heed should be given in the protracted conservative management

how permanent the results of such treatment may be. Secondly, the patient is instructed to eat his way out of his troubles — diet. And thirdly, surgery is invoked with the hope that this expedient will ensure a more lasting cure than that achieved by the two preceding agencies.

As a surgeon, it would be presumptuous of me to attempt to discuss any but the last aspect of this problem.

Indications for Operation

In our clinic, 80 per cent of patients undergoing resection for ulcer have had one or more of the conventional complications of ulcer, including perforation, hemorrhage and obstruction. In our experience, the typical patient accepting resection for ulcer is a man in the middle forties whose symptoms trace back fifteen years. Inasmuch as the patients come largely from the rural areas of Minnesota, the typical patient is a farmer whose work should not be especially conducive to the ulcer diathesis. Moreover, I have been unable to observe in these patients any common behavior pattern, which the routine employment of psychiatric technics might uncover, nor can I see any such uniform physical conformation in ulcer patients as was formerly described under the designation "ulcer habitus."

In this clinic, only 2 patients under twenty years of age have undergone resection for ulcer. One was a boy of fourteen who first suffered a severe hemorrhage from a duodenal ulcer at the age of ten. After an interval of four years, during which many such occurrences threatened his life, a three-quarter resection was undertaken in the presence of massive hemorrhage. More than six years have elapsed, and the boy has grown to manhood. There has been no suggestion of recurrence. The other patient was a nineteen-year-old boy with repeated massive hemorrhages from a duodenal ulcer. He too has remained well.

Approximately a dozen patients in their twenties have been subjected to resection for ulcer. Patients in their thirties are more numerous, and a fairly large number first developed symptoms in the sixth or seventh decade of life. Several patients in their eighties have submitted to resection for ulcer because of compelling indications for operation, or because of long continued dissatisfaction with medical management.

Perforation There can be no disagreement concerning the manner of treatment of perforation. This complication has been an important element in the mortality of ulcer. Yet considerable improvement has resulted from the following methods of dealing with perforated ulcers: the use of unabsorbable (silk) sutures, employing Graham's¹¹ technic of placement of the sutures, lavage of the peritoneal cavity with copious quantities of physiologic saline solution, and the use of chemotherapy. Whereas the general mortality from acute perfora-

tion still hovers around 20 to 25 per cent, in institutions where the above precepts guide the therapy, the mortality is approximately 5 per cent.

Hemorrhage There is room for considerable improvement in the management of hemorrhage attending ulcer. Allen and Benedict¹² were responsible for persuading American surgeons to operate in an attempt to save the lives of patients suffering from massive hemorrhage. The difficulties relating to the problem are many. The decision whether operation should be undertaken is not easily made. Often, too much time is lost by attempts to replace blood loss that is continuing. When a patient has repeatedly been in shock, he is not a good candidate for operation. Physicians and surgeons would do well to consider operating immediately on patients who have a long history of ulcer with previous hemorrhages. The problem may be difficult or other scores. The diagnosis may be in doubt. Gastric cancer, in the experience of our clinic, is not an infrequent cause of sudden massive hemorrhage. And the technical problem in a duodenal ulcer with a large crater may be extremely difficult. The situation usually demands that the duodenum be cut across to find and arrest the source of hemorrhage, then, there remains the extremely difficult task of obtaining a satisfactory closure of the open duodenum — a problem that may be perplexing especially in the large supraduodenal ulcer crater with perforation into the hepatoduodenal ligament. A number of studies suggest that the mortality in patients treated medically for massive hemorrhage is in the neighborhood of 10 to 13 per cent.¹³ Early resort to surgery will spare the lives of many such patients who will otherwise die from exsanguination. In the patient who presents both obstruction and massive hemorrhage, the indication for early surgery is especially imperative.

In this connection, it is probably not out of place to indicate that, in certain cases, the cause of the bleeding remains occult at operation. On the thesis that such bleeding comes usually from a small mucosal erosion that cannot be felt through the gastric wall, I have resected a number of stomachs for massive hemorrhage. Several of these case histories have been reported in detail elsewhere.¹⁴ The situation of fatal bleeding from a single small mucosal erosion in the stomach is well known to pathologists. The condition may be passed over by the surgeon at operation. In cases of massive loss of blood by vomiting, when the surgeon fails to find a likely source for the difficulty, the possibility of a superficial gastric erosion should not be overlooked.

Moreover, bleeding in portal hypertension may also be amenable to correction by gastric resection. It has been taught that the chief source of bleeding is ruptured esophageal varices. Inasmuch as obstruction of the superior vena cava may also give rise to esophageal varices unaccompanied by hemor-

patient. At the time of the first gastric resection only a small section of stomach (155 gm), including 6 cm of jejunum, which was not weighed separately, was removed, if this segment is considered to have weighed 20 gm, a section of stomach weighing only 135 gm was removed — too small an amount for the usual resection. The primary difficulty is, however, that stout men of hypersthenic build have a short transverse stomach whose fundus closely tethered to the left diaphragm and the spleen. In other words, in a thin patient whose stomach hangs down in the form of a fishhook, it is not a difficult task for the surgeon to remove the requisite amount of stomach. In an obstructed patient, the usual weight of the excised gastric tissue in a three-quarter resection is 150 gm. In patients with obstruction the weights of such excised specimens obviously run considerably higher. In the patient with the recurrent stomal ulcer on whom I reoperated, an additional 86 gm of gastric tissue was removed. He has remained well.

The policy in our clinic has been to do a one-stage procedure, taking time to do what needs to be done. There is little justification for performing an inadequate operation such as gastrojejunostomy²⁰ in the difficult cases, electing to perform gastric resection only in those patients in whom it may be performed without difficulty. Moreover, in difficult duodenal ulcers a choice need not lie between a compromise measure, such as gastrojejunostomy with an admitted incidence of stomal ulcer of 15 per cent, and a resection that risks the continuity of the common bile duct and requires a tube in the duct.²¹ The antral mucosa can be excised, the pyloroantral muscle cylinder being left. The experience of our clinic is that such an operation can be done with a reasonable risk, and the ultimate promise of success is the same as in the straightforward gastric resection.²² As a matter of fact, in these difficult operations, performed on somewhat less than 100 patients, there have been no stomal ulcers. The objection to more universal adoption of the pyloric exclusion operation, with excision of the antral mucosa, has been fear of leakage through the segment with the development of a subphrenic abscess.

THE DUMPING SYNDROME

One of the disturbing items accompanying gastric resection has been the occurrence in some patients of what might be described as the "dumping syndrome," which is frequently observed in all patients soon after operation but persists in a few or long periods. Whether these symptoms are physiologic or psychologic is difficult to determine. Dr David Gaviser²³ has been at work in this clinic on the problem for some time, and it is hoped that some enlightenment may be shed on its mechanism. Loss of the pyloric sphincter in gastric resection permits quick filling of the jejunal segment, a cir-

cumstance against which the pylorus ordinarily affords protection. Sudden dumping of the contents of the stomach into the jejunum may be accompanied by nausea, pain and vomiting. Eating slowly and in small amounts at a time, and the avoidance of drinking with meals, ameliorates the symptoms considerably. In most cases the time factor adjusts the situation satisfactorily. The frequency with which milk and cream are shunned by the ulcer patient after gastric resection suggests that the problem merits investigation.

Moreover, some patients undergoing gastric resection for ulcer, particularly those who were thin prior to operation, manifest some difficulty in maintaining weight. Whether this circumstance is due to difficulty with food ingestion or to absorption is not known. Metabolic studies should be made in a few such patients to determine whether the operation has interfered with the assimilation of protein and fat.* Serious anemia has not been observed after the three-quarter resection for ulcer.

* * *

It is not known whether the margin of difference between a patient having an ulcer and another without ulcer, whose stomach responds normally to extrinsic stimuli, is wide or narrow. No means of measuring this difference have been determined. Whether the difference is qualitative or quantitative and primarily concerns factors of secretion or tissue resistance to acid-peptic erosion is also not known. I am inclined to believe that the latitude of difference between a patient with ulcer and another without ulcer is not great. In other words, patients whose stomachs secrete normally may be tight-rope walkers so far as the ulcer problem is concerned and may, with slight provocation, be catapulted into ulcer difficulties. The great advantage of a slightly superior force is well documented in biology. The lungs are kept expanded by a force that is less than 1 per cent of the major operating force, atmospheric pressure.

Ulcer can be produced by stimulating an animal's endogenous gastric secretory mechanism with histamine. Moreover, agencies that favor the occurrence of anoxic areas in the gastric mucosa encourage the ulcer diathesis.

The three-quarter (75 per cent) gastric resection protects against the ulcer provoked by histamine in beeswax in the dog. Employment of a long afferent duodenojejunal loop in such an anastomosis invites stomal ulcer. Vagotomy fails to protect against the histamine-provoked ulcer in the dog, rabbit and cat. The Sippy diet fed through a gastrostomy tube to dogs receiving histamine in beeswax affords protection against the development of ulcer.

*Wallace and his associates at the Mayo Clinic have recently reported carrying out such studies (Forum on Fundamental Surgical Problems, Cleveland, December 19, 1946). They observed unusually large amounts of fat in the stools of some patients who experienced difficulty in maintaining their weight after a Billroth II type of gastric resection for ulcer.

of any patient with a persistent gastric ulcer, is that the possibility of malignancy cannot be completely excluded. In prepyloric lesions, in particular, this is an important consideration — so important, I believe, that in all patients with such defects the item of malignancy should be carefully weighed. The roentgenologist should appreciate how much the nature of his report determines or influences the course of action in such patients.

SHORTCOMINGS OF SURGERY

Dissatisfaction with the accomplishments of surgery in the ulcer problem is also real. The distrust of internists, actuaries and military authorities in the ability of surgeons to rehabilitate medical failures of ulcer management by surgical treatment is well known. Surgeons, obviously, have been too empirical in their approach to the ulcer problem, endorsing and employing procedures without a clear-cut definition of the criteria of an acceptable operation for ulcer. Let anyone who suggests a new operation for ulcer that is not founded on sound physiologic principles beware of the hazards of premature judgment! The late Lord Moynihan stated that the accomplishments of gastrojejunostomy stamped it as one of the great operations devised by surgeons for the relief of ulcer. What empty words in the light of critical experience!

AN ACCEPTABLE OPERATIVE PROCEDURE

The histamine-in-beeswax technic has proved a useful instrument in defining the criteria of an acceptable operation for ulcer. A three-quarter (75 per cent) gastric resection made with a short afferent duodenal loop affords consistent protection against the histamine-provoked ulcer in dogs when other abetting influences are not employed simultaneously. Gastrojejunostomy and the small gastric resection (less than 50 per cent) fail consistently. The experimental evidence of the necessity of employing a short afferent duodenojejunal loop to protect against recurrent ulcer appears complete. The Billroth I procedure apparently necessitates the same extent of resection (75 per cent) as a satisfactorily performed Billroth II operation to protect against the histamine-provoked ulcer.¹⁰ In man, excision of the antral mucosa is a necessity, failure to remove the mucosa, even despite an otherwise adequate gastric resection, invites a stomal ulcer. Vagotomy also fails to protect against the histamine-provoked ulcer. Inasmuch as histamine acts directly on the parietal cells in the gastric tubules, no such protective action of histamine from vagotomy is perhaps to be anticipated. Hartzell¹⁷ studied the effect of bilateral vagotomy on gastric secretion in the dog. During the five-month interval following operation, Hartzell noted a distinct reduction in the gastric secretory response to ingested meat. Vanzant¹⁸ restudied the remote results of vagotomy in 4 of Hartzell's 8 dogs more than two years after the

vagotomies had been done. At that time, Vanzant noted that the depressing effect of vagotomy on gastric secretion had been lost. The cephalic-psyche phase of gastric secretion, which is ablated by vagotomy, may be a vital factor in the spontaneous occurrence of ulcer in man. That the cephalic phase of gastric secretion may be more important in man than in the dog is difficult to believe, when one observes the eagerness of a hungry dog anticipating a piece of meat. In any event, the observations of Dragstedt¹⁹ and his associates will be followed with the keenest interest by all who are concerned with the problem. Vagotomy, however, is not an experiment that should be undertaken simultaneously in many quarters. Dragstedt will be able to determine in reasonable time whether the results in man are abiding.*

SURGICAL CURE

A successful operation for ulcer must not compromise the future for the patient by holding over him the threat of recurring ulcer. That, in the main, has been the indictment against operations for ulcer, it is a just criticism. A satisfactory operation for ulcer, in addition, in the hands of experienced surgeons, should carry a risk to life that is less than that of the disease for which operative relief is undertaken. Furthermore, it should hold out to the patient relief from distress and from the monotony of dietary strictures. An acceptable operation for ulcer should impose no significant new difficulties on the patient.

It is well known that patients with gastric ulcer are more readily cured of the ulcer diathesis by surgery than patients with duodenal ulcer. Similarly, women appear to be more easily amenable to cure by operation than men, in whom ulcer is far more frequent.

RESULTS OF OPERATION

The experience of this clinic is that gastric resection for ulcer, as described below, can be carried out in elective operations at a risk of 2 or 3 per cent. The over-all mortality, including that in emergency operations for perforation and massive hemorrhage, has been 5 per cent. In more than 500 consecutive patients who have had resections for ulcer performed over an eight-year period, there have been 2 cases of stomal ulcer, both of which occurred in heavy men, short in stature and of stocky, hypersthenic build. Both patients had undergone an earlier gastrojejunostomy for bleeding duodenal ulcer elsewhere. Both patients have severe hypertension. One of them has done well, with a partial return to some of the dietary strictures to which he submitted before operation. I have operated again on the

*In a paper presented before the St. Paul Surgical Society on January 15, 1947, by Dr. Waltman Walters and his associates of the Mayo Clinic, little support was lent to the thesis that vagotomy is a satisfactory primary operation for ulcer. They reported failure of the ulcer to heal following vagotomy as well as cases of hemorrhage and perforation. Such occurrences do not augur well for the future of vagotomy.

side or the other. Yet it may be substernal, a strong element of distress or gripping. It is less specific, perhaps, than pain and is not significant when combined with hemoptysis, which is extremely important if present, although a diagnosis is often made without it. When associated with cardiac failure, it strongly suggests embolism. Shortness of breath is associated with the severer cases of embolism, especially when there is other evidence of right-sided cardiac embarrassment. It is not although it may lead rapidly to death, its persistence for many hours or even days is not inconsistent with complete recovery. Pulmonary and peripheral congestion, as signs of cardiac failure, are frequently noted in medical cases.

Associated symptoms and signs of thrombosis in the legs are observed with a frequency proportional to the diligence with which they are sought. They are best seen against a background of preliminary routine observations and, since even a bilateral thrombosis is rarely symmetrical, by comparison of one leg with the other. Subjective complaints usually take the form of pain, referred to some part of the calf and, as a rule, accompanied by local tenderness of a deep sort, particularly on the outer anterior face of the lower leg. Objective signs of thrombosis are related to the state of the great muscles. The earliest are slight increase, by measurement, of the largest diameter of the calf, an increased firmness or elasticity on compression and a tendency to resist dorsiflexion. Signs of venous engorgement are not to be expected in bed patients at slight cyanosis of the foot may be evident on standing or even on hanging a leg out of bed and edema, on more prolonged dependency.

An elevation of the pulse rate and temperature — a clue that is especially emphasized by Bauer¹⁻³ and by Allen and his associates^{4, 5} — is most frequently obtained from a surgical chart that has previously leveled off following an operation or injury. It appears to be seen less often in patients with cardiac disorders and other serious illnesses. It may well represent early, preclinical pulmonary embolism.

Circulatory failure of some degree — that is, faintness or actual loss of consciousness — may result reflexly from any infarction. The general circulation may react rather violently to the lodgment of an embolus, and yet may readjust itself within a few hours if no further insult occurs.

Roentgenologic evidence of pulmonary infarction, if obtainable, is of primary importance, as Hampton and Castleman^{6, 7} have demonstrated. But the infarct, although entirely characteristic, if a proper exposure can be secured for the x-ray film shows poorly in plates taken in bed. It is therefore best seen in ambulatory patients deliberately studied, of course, not all emboli cause infarction, owing to the unpredictable efficiency of the collateral pulmonary circulation.

Electrocardiographic signs, which are for the expert, may be pathognomonic, especially soon after the embolus has lodged. Sometimes, exclusion of coronary thrombosis indicates an unsuspected pulmonary embolism.

With such aids to diagnosis in mind, pulmonary embolism can be identified in a surprisingly large number of cases. Undoubtedly, the profession is becoming increasingly alert to its presence. Given a suggestion that embolism has occurred, the slightest sign of thrombosis in the legs is confirmatory. But even without such confirmation, the diagnosis can be made by a study of the nature of the attack or attacks, checked by roentgenologic and cardiographic evidence. Note should, of course, be taken of fatal embolism, but nonfatal forms are more worthy of study.

PHLEBOTHROMBOSIS (QUIET THROMBOSIS) AND THROMBOPHLEBITIS

Thrombosis in the veins of the legs should not be regarded as too mysterious a disease. Unfortunately, like many other disorders, it was first recognized in its late, advanced stage — in this case, the unmistakable state of venous obstruction familiar to all as phlebitis or phlegmasia alba dolens. This outspoken state should, for the moment, be forgotten or regarded as an end-result, a thrombotic occlusion of the femoral and iliac veins. It carries a threat of many disagreeable aftereffects but little danger of embolism. It is rather on the early quiet or bland stage, from which Bauer,¹⁻³ by phlebographic studies, has proved that it develops, that one should concentrate. This Ochsner⁸ has called "phlebothrombosis."

I can do no better than quote from an address of Dr. Lewis A. Conner,⁹ in which he recalls his experiences of many years ago with the thrombophlebitis of typhoid fever:

It was found that, by careful daily examinations of the lower extremities of every typhoid patient throughout the course of the disease, it was possible to recognize a beginning thrombosis, often many days before the classic symptoms of femoral thrombophlebitis appeared, and to recognize also many minor forms of thrombosis that recur, at any time developed the picture of phlegmasia alba dolens.

He found pain and soreness on stretching of the calf muscles, a small area of tenderness or, less often, tenderness and induration about the heel and deep in the sole. Following the discovery of such signs, phlegmasia alba dolens might develop in several days to several weeks.

Today's observations have added something. In patients who are to be particularly observed, the calves and ankles are carefully measured — the smallest circumference at the ankle and the largest in the swell of the calf are sufficient — before they undergo the experience, operative or other, that it is thought may lead to a lower-leg thrombosis, special attention should be given to patients over fifty years of age. Each day these observations are

An ulcer operation tested in the experimental laboratory against the powerful capacity of histamine to provoke ulcer in dogs has proved successful for combating the ulcer diathesis in man. The important components of such an operation are extensive gastric resection (75 per cent), employment of a short afferent duodenojejunal loop, a retrocolic anastomosis being made at the suspensory duodenojejunal ligament, and excision of the antral mucosa. Failure on the part of the surgeon to observe all these elements of a satisfactory resection may invite a stomal ulcer. Consistent meeting of these criteria by the surgeon in every gastric resection performed for ulcer will dispel the myth of the intractable ulcer.

Although the prospect of an operation that will preclude recurrent ulcer may be heartening to both patient and surgeon, it is to be hoped that further study will uncover methods of achieving the same end by lesser means. Dispensable as the stomach appears to be, the outlook to ulcer sufferers would be brighter if simpler means were devised to overcome the ulcer diathesis, permitting the patient to keep his stomach intact. Surgeons must continue to be realists, however, wishing-wells are not a solution to the problem. Until a more adequate operation than gastric resection is available, the problem of ulcer must be faced in the light of present knowledge.

VENOUS THROMBOSIS AND PULMONARY EMBOLISM*

JOHN HOMANS, M.D.†

BOSTON

PULMONARY embolism, once regarded as an unavoidable accident of surgery, today preoccupies the minds of many clinicians, physicians and surgeons alike. For it is recognized as a threatened complication in the great field of serious diseases, injuries and operations that depress the patient and enforce life in bed.

In the last decade, pathologists have shown that when post-mortem examinations of the legs are thoroughly made, thrombosis is found in the deep veins of the calf in nearly 50 per cent of all cases at autopsy. Much of this thrombosis is terminal and in no sense a cause of death. Yet it fits in with clinical experience in calling attention to a process, relatively frequent in the hospitalized patient, that may readily become a source of embolism.

In the study of thromboembolic disease, it will be convenient to consider first embolism and,

secondly, the diagnosis and treatment of venous thrombosis in the lower limbs.

PULMONARY EMBOLISM

On the clinical side, pulmonary embolism is being recognized by symptoms and signs often regarded in the past as indications of primary disease of the heart and lungs or perhaps as commonplace complaints having no special significance. Hardly any one sign is, in itself, authoritative. It is the combined evidence from several sources that makes the diagnosis, and although in different clinics—those prevalently medical or surgical, for example—emphasis is apt to be placed on one or another group of symptoms, the relative significance of the clinical changes pointing to embolism is indicated in the order of the following paragraphs.

Thoracic symptoms and signs may be expected in about 50 per cent or more of all cases. Pain, although not universal, is the most frequent symptom, it usually takes a pleuritic form, being referred to

†Surgeon emeritus, Peter Bent Brigham Hospital.

just as successfully by the Swedish school, in reduced doses, three or four times a day. And recently Loewe¹² has shown that reasonably good results can be secured by introducing it intramuscularly in Pitkin's menstruum. Dicumarol, the newer coagulant, acts on the liver to prevent prothrombin formation. Being inexpensive and effectively absorbed when taken by mouth, it is tending to displace heparin. Its successful use at the Mayo Clinic is reported by Barker, Cromer, Hurn and Hughes¹³. Its dosage, however, is almost more difficult to gauge. The same dose in one patient may lower the prothrombin percentage (prolong prothrombin time) dangerously, provoking hemorrhage from the intestinal or genitourinary tract or causing excessive arterial oozing following surgical operation, and yet in another patient it causes no appreciable change in the prothrombin level. Its administration requires experience, skill and daily laboratory analysis of the blood.

Of the two drugs, dicumarol more urgently demands hospital care. Since its withdrawal leads to immediate restoration of prothrombin, vigorous administration of hykinone (artificial vitamin K) is called for if serious hemorrhage is present or threatened.

With such considerations in mind, the anticoagulants may profitably be used as follows: postoperatively for patients over fifty years of age, when no second-stage procedure is contemplated, especially for those subjected to serious abdominal and pelvic operations, but heparin should not be given within seventy-two hours of the operation nor dicumarol within perhaps forty-eight hours. Doubtless, the postoperative uncontrolled period should vary in length with the nature of the operative field, for coronary thrombosis, not only for their effect in preventing the thrombosis in the legs incidental to enfeeblement and confinement to bed but also for their favorable influence on thrombosis in the heart's wall and within its chambers. Wright¹⁴ reports favorably on such treatment.

Vein interruption. Bilateral femoral-vein ligation or section can be recommended for prophylactic purposes in patients over fifty years of age as a preparation for operation in cases of cancer, prostatism and other serious diseases, particularly when a several-stage operation is contemplated, and in the treatment of fractures of the lower limbs requiring immobilization and prolonged treatment, particularly in the affected leg. The femoral vein should be sectioned distal to the profunda branch, for Allen and his associates^{4, 5} find that, at this level, protection against embolism is obtained without noticeable disturbance of the venous return.

Definitive Treatment

One can obtain encouraging evidence in favor of either operative or anticoagulant therapy according to different groups of clinicians. At present, the

trend of medical opinion seems to favor the anticoagulants, but surgical interruption of the venous tree, at one level or another, has a fascinating definiteness that is brought out in the reports from certain hospital centers. I shall attempt to present the problem from several points of view.

Anticoagulants. Bauer¹⁻³ and others of the Swedish school, basing their opinion mainly on postoperative and traumatic cases, hold that heparin, given only on the establishment of an early diagnosis of lower-leg thrombosis by methods that include phlebography, is remarkably effective in controlling not only the local process but also any embolism that may already have occurred. Heparin is given intravenously, in separate doses of 150 mg or less, at regular intervals, without laboratory examinations of the blood. All who have studied their work have been greatly impressed. The Swedish Government furnishes the heparin at a minimal charge — a most important consideration. Recently, dicumarol has been taken up. In the United States this drug is displacing heparin, partly because of its relative cheapness but also because of its greater ease of administration. Whether the intramuscular or subcutaneous use of a menstruum from which heparin can slowly be absorbed will make the older drug as generally acceptable as dicumarol remains to be seen.

Those who believe in treating established venous thrombosis by anticoagulant therapy use it whether or not pulmonary embolism has already occurred, holding that it controls further detachment of thrombus and also prevents thrombosis secondary to the presence of emboli in the pulmonary vessels, favoring healing of the infarct in the lung. Evidently, anticoagulants do not always dispose successfully of the soft, insecure, propagating thrombi in the veins of the lower limb, since fatal embolism has been known to occur on their withdrawal and even during their administration. They appear, however, to render harmless and to heal the thromboses that have not as yet caused embolism, particularly when the process seems to be confined to the lower leg. Thus, they should and probably do, prevent the extension of many thrombi into the popliteal and femoral veins, preserving the useful valves of those vessels.

Anticoagulants, then, may properly be preferred in the treatment of established thrombosis, when laboratory facilities are available and when the conditions calling for treatment are neither continuing nor recurrent, in thrombosis occurring in active life, in early postoperative and post-partum processes apparently confined to the lower leg and in thrombosis associated with any severe brief illness including coronary infarction.

When embolism has already occurred at any stage of thrombosis, the anticoagulants may still be used, although surgical interruption is probably to be preferred, as pointed out below.

repeated. Instead of feeling soft and relaxed, one calf may seem slightly more firm to the grip of the fingers and may prove to be somewhat larger than the other. The muscles may be somewhat irritable, a state brought out by putting the posterior group on the stretch. Deep tenderness may be present along the course of one of the major vessels or perhaps in the popliteal space. But it should be remembered that among the great muscles of the lower leg there are plexuses of veins in great ladder-like systems, in which thrombosis can be tucked quietly away, giving no signs until it becomes so extensive as to occasion discomfort or provoke resistance when the muscles are squeezed or stretched, or until it reaches the popliteal vein, where it may sufficiently obstruct the blood flow to cause edema and cyanosis of the ankle and foot. Yet even these latter signs need not be seen in the patient entirely confined to bed.

A useful proof of deep thrombosis, insufficiently appreciated, is the presence of a thrombosed area in a superficial vein, particularly on the back of the calf. The hardened stretch of vein is all the more noticeable, as a rule, because no varicosity is present as an excuse for a local thrombus. Such a thrombosed vessel is often part of the lesser saphenous system, which communicates freely with the fibular (peroneal) vessels.

It cannot be too strongly emphasized that the more silent and insidious the deep thrombosis, the more dangerous it is, and the more outspoken, the less liable to cause embolism. In a bilateral disease, for example, when one leg is tensely swollen and the other seemingly normal, embolism is threatened less by the swollen limb than by the apparently innocent one. But although any one thrombosis may have more of an inflammatory character, as marked by pain and soreness, than another, all tend to advance in the end toward a femoriliac obstruction. Death, in the early stage, will occasionally occur, or the thrombosis may progress so slowly that it permits a current, of a sort, to pass it for a long time. Basically, there is no true distinction between a quiet thrombosis or phlebotrombosis and the familiar thrombophlebitis, although treatment of the two is somewhat different, and since I am dealing with the thromboembolic problem, I shall devote myself to the quiet, early stage of the disease.

TREATMENT OF THROMBOEMBOLIC DISEASE

It would be ideal if, in every case of early, deep venous thrombosis, the likelihood of embolism could be known—if, for example, one could say that among 100 cases of thrombosis in the lower leg, 10 to 20 were likely to develop embolism and again, that among the 10 to 20 cases of embolism 3 to 5 would be fatal. Such figures are, perhaps, not far from the facts, but from different clinics come various percentages. Among the general run of

postoperative patients, one may expect a higher incidence of thrombosis and embolism than is observed in a group that includes cardiac, prostatic and other extremely ill and elderly persons. Moreover, the diagnosis of venous thrombosis is still a little standardized that consistent figures should not be expected. Again, the age grouping is most important, since embolism, and especially fatal embolism, begins to be seriously threatened only in late middle and advanced age. One had better recognize that in patients committed to bed by operation, accident and serious illness, thrombosis may be encountered so often that it must always be kept in mind, and one should expect embolism, in a mild or serious form, to occur fairly frequently in the early stage of thrombosis. Prophylactic and definitive treatment are based on these considerations.

Prophylactic Treatment

At various times, an astonishing variety of proposals for preventing venous thrombosis in surgical cases has been made, from deep breathing to the giving of dried thyroid gland. Obviously, the first consideration is that the normal activities of the patient should be interrupted as little as possible or, if interrupted, should rapidly be resumed. The term "early ambulation" includes everything intended to restore physiologic normalcy. It cannot be fully protective, since quiet thrombosis may occur without known cause in everyday life, even in young people. Moreover, the very nature of the disease, operation or injury may enforce considerable immobility. Nevertheless, heart disease, most fractures and all surgical operations are now treated with far less confinement to bed than formerly. Above all, the sitting or reclining position in bed, while the legs are relaxed, is to be avoided. And as often as possible the legs must actively be exercised, preferably in elevation, with the aid of an attendant, but if such aid is not at hand, by voluntary contraction and relaxation of muscles by wiggling of the toes and by describing a circle with the forefoot.

Elevation of the foot of the bed favors a return of circulation and avoids venous stasis. Combine with exercise in bed, this procedure has a favorable influence on thrombosis already established. It should therefore be useful as a preventive measure.

Anticoagulants The nature of these chemicals is undoubtedly well known. Heparin, an expensive preparation, acts directly on the blood, delaying coagulation. Its effect is noted by the degree to which the clotting time is prolonged, and since it is rapidly eliminated, the drug must frequently be introduced. Even when administered by continuous intravenous drip, as was done at first both by Murray¹⁰ and by Crafoord,¹¹ it cannot be said to produce an ideal, steadily maintained delay of coagulation for fifteen to twenty minutes (by bedside tests). Actually, it has since been given

t as successfully by the Swedish school, in doses, three or four times a day. And Loewe¹² has shown that reasonably good results can be secured by introducing it intramuscularly in Pitkin's menstruum. Dicumarol, the newer anticoagulant, acts on the liver to prevent prothrombin formation. Being inexpensive and effectively absorbed when taken by mouth, it is tending to replace heparin. Its successful use at the Mayo Clinic is reported by Barker, Cromer, Hurn and Hargraves¹³. Its dosage, however, is almost more difficult to gauge. The same dose in one patient lowers the prothrombin percentage (prolongs the prothrombin time) dangerously, provoking hemorrhage from the intestinal or genitourinary tract or causing excessive arterial oozing following surgical operation, and yet in another patient causes no appreciable change in the prothrombin level. Its administration requires experience, skill and daily laboratory analysis of the blood.

If the two drugs, dicumarol more urgently demands hospital care. Since its withdrawal leads to immediate restoration of prothrombin, vigorous administration of hykinone (artificial vitamin K) is called for if serious hemorrhage is present or threatened.

With such considerations in mind, the anticoagulants may profitably be used as follows: postoperatively for patients over fifty years of age, when no second-stage procedure is contemplated, especially for those subjected to serious abdominal and pelvic operations, but heparin should not be given within seventy-two hours of the operation nor dicumarol within perhaps forty-eight hours—subtly, the postoperative uncontrolled period should vary in length with the nature of the operative field, for coronary thrombosis, not only for their effect in preventing the thrombosis in the legs incidental to enfeeblement and confinement to bed but also for their favorable influence on thrombosis in the heart's wall and within its chambers. Knight¹⁴ reports favorably on such treatment.

Vein interruption. Bilateral femoral-vein ligation or section can be recommended for prophylactic purposes in patients over fifty years of age as a preparation for operation in cases of cancer, prostatic disease and other serious diseases, particularly when a several-stage operation is contemplated, and in the treatment of fractures of the lower limbs requiring immobilization and prolonged treatment, particularly in the affected leg. The femoral vein should be sectioned distal to the profunda branch, for Allen and his associates¹⁵ find that, at this level, protection against embolism is obtained without noticeable disturbance of the venous return.

Definitive Treatment

One can obtain encouraging evidence in favor of either operative or anticoagulant therapy according to different groups of clinicians. At present, the

trend of medical opinion seems to favor the anticoagulants, but surgical interruption of the venous tree, at one level or another, has a fascinating definiteness that is brought out in the reports from certain hospital centers. I shall attempt to present the problem from several points of view.

Anticoagulants. Bauer¹⁻³ and others of the Swedish school, basing their opinion mainly on postoperative and traumatic cases, hold that heparin, given only on the establishment of an early diagnosis of lower-leg thrombosis by methods that include phlebography, is remarkably effective in controlling not only the local process but also any embolism that may already have occurred. Heparin is given intravenously, in separate doses of 150 mg or less, at regular intervals, without laboratory examinations of the blood. All who have studied their work have been greatly impressed. The Swedish Government furnishes the heparin at a minimal charge—a most important consideration. Recently, dicumarol has been taken up. In the United States this drug is displacing heparin, partly because of its relative cheapness but also because of its greater ease of administration. Whether the intramuscular or subcutaneous use of a menstruum from which heparin can slowly be absorbed will make the older drug as generally acceptable as dicumarol remains to be seen.

Those who believe in treating established venous thrombosis by anticoagulant therapy use it whether or not pulmonary embolism has already occurred, holding that it controls further detachment of thrombus and also prevents thrombosis secondary to the presence of emboli in the pulmonary vessels, favoring healing of the infarct in the lung. Evidently, anticoagulants do not always dispose successfully of the soft, insecure, propagating thrombi in the veins of the lower limb, since fatal embolism has been known to occur on their withdrawal and even during their administration. They appear, however, to render harmless and to heal the thromboses that have not as yet caused embolism, particularly when the process seems to be confined to the lower leg. Thus, they should and probably do, prevent the extension of many thrombi into the popliteal and femoral veins, preserving the useful valves of those vessels.

Anticoagulants, then, may properly be preferred in the treatment of established thrombosis, when laboratory facilities are available and when the conditions calling for treatment are neither continuing nor recurrent, in thrombosis occurring in active life, in early postoperative and post-partum processes apparently confined to the lower leg and in thrombosis associated with any severe brief illness including coronary infarction.

When embolism has already occurred at any stage of thrombosis, the anticoagulants may still be used, although surgical interruption is probably to be preferred, as pointed out below.

Surgical interruption of veins This method, decidedly favored in this part of the country, has a most attractive quality in that, if ideally performed, it ends all danger of embolism. Its success depends greatly on early diagnosis and exact localization of the thrombus. A distinct advantage is the ease with which the upper femoral vein can be reached under procaine infiltration, so that a general anesthetic is avoided. A disadvantage is the resulting rather sudden venous obstruction at what may be called the common femoral bottleneck, especially when many deep veins in the lower leg and thigh are already more or less occluded by thrombosis. Then, the collateral pathways, adequate in early, local thrombosis, are decidedly insufficient. Yet if the femoral vein is ligated below (distal to) the great branch entering from among the muscles of the thigh (*profunda*), thrombosis may, although rarely, to be sure, short-circuit the obstruction with a fatal result. Anticoagulants may be combined with a superficial femoral section to prevent such an accident, although a period of several days must obviously elapse after the operation before the drugs can be administered. Another disadvantage, which is true of every femoral-vein section for established thrombosis, is that the operation throws out of function the important valvular system of the femoral vein, whether or not the process has already occupied that vein. Thus, even if a thrombus in the calf heals without extension, a considerable readjustment of the venous circulation is required. Actually, in some cases, the local thrombus seems to spread following femoral-vein section, increasing muscular irritability in the lower leg and enforcing a minutely governed and rather prolonged convalescence—a matter too seldom realized by either patients or surgeons.

In spite of such objections as the above, bilateral interruption of the femoral vein should be performed in all cases when anticoagulants cannot be given with proper controls and is a preferred alternative to the use of anticoagulants when thrombosis has advanced into the thigh (as shown by local signs and a considerable duration of the disease), especially when embolism has already occurred. This second indication applies to a great group of cardiac patients, bad fractures in the elderly and postoperative cases in general.

As for the level at which the femoral vein is sectioned, the common femoral vessel, proximal to the *profunda*, for reasons already explained, must be preferred. Into this large vessel a smooth glass tube can be introduced to suck out detachable thrombus. In this way, even the common iliac vein can often be cleared.

Those who believe in performing this operation, even when an obstructive thrombophlebitis is present, hold that the extraction of thrombus from the obstructed and inflamed vein not only lessens such danger of embolism as may exist but also acts

favorably, much as does sympathetic lumbar block by procaine, on the secondary vasoconstriction it causes so much discomfort and edema. This procedure is perhaps well taken, — although the advocates of lumbar sympathetic block maintain that the considerable surgical procedure was unnecessary, — but in any event femoral exploration and section prevent recanalization of the disabled femoral vein and encourage from the beginning a collateral circulation.

Higher interruptions — of the common iliac vein or vena cava — are sometimes desirable. Ligation of the common iliac vein should be used for recurrent persistent processes believed to be confined to the leg. I¹⁵ have elsewhere given reasons for holding that it offers a collateral circulation decidedly better than is permitted by a common femoral interruption. The approach to both common iliac vessels extraperitoneal, requiring a general anesthetic, is sometimes difficult, especially on the left.

Ligation of the vena cava is a last resort in the presence of otherwise uncontrollable embolism, especially when the causal thrombosis is bilateral and unlocalizable. Although statements to the contrary are often made, the operation is one requiring experience and skill in approaching and handling large blood vessels. At times, it must be accepted as superior in effectiveness to any other procedure, operative or medicinal.

* * *

This discussion has perhaps left a sense of confusion. Should the anticoagulants or operative procedure be preferred as the ideal treatment for threatened actual venous thrombosis and for threatened actual embolism? I recognize that the present trend is toward a greater use of the anticoagulants. If far this tendency will go, I am unable to say. At the moment, I have offered a reasonable scheme for making use of one method or the other, observing that in some circumstances there is a choice between them. On behalf of surgery, I beg that it be employed only when it is fully understood what particular operative procedure may be expected to accomplish. I urge that the anticoagulants be used only when accurate, routine blood studies are available. Undoubtedly, as experience widens, definite indications for the use of operative or clinical methods of preventing and treating thrombosis in the veins of the lower limbs will be available.

THE SIGNIFICANCE OF EOSINOPHILIA IN ABDOMINAL COMPLAINTS OF AMERICAN SOLDIERS

ERIC DENHOFF, M D *

PROVIDENCE, RHODE ISLAND

IN THE Southwest Pacific the characteristics of many tropical diseases acquired by American soldiers differed from those described in textbooks. Medical officers suspected new syndromes, but laboratory personnel were frequently unable to confirm these impressions with routine methods. The lack of specific diagnostic evidence often forced diagnosis of psychoneurosis. In the course of time, it was possible to evaluate certain criteria and to devise practical technics that were helpful in differentiating the neurotic patients from those with usual manifestations of the usual tropical diseases. Some of these methods have been described in previous publications. For example, the proper interpretation of chromatin dots and pigmented leukocytes in thick smears stained in an unconventional manner helped confirm the diagnosis of malaria in a substantial number of patients with vague, non-specific febrile reactions.¹ Attention to the significance of high degrees of eosinophilia aided in establishing a diagnosis of filariasis when clinical criteria were lacking.² In a large group of patients with gastrointestinal disorders, controlled studies utilizing practical technics helped differentiate functional from organic disorders.^{3, 4} A study of hematology values clarified the significance of eosinophilia in American soldiers.⁵

After thirty-six months of clinical and laboratory experience in the tropics, the evidence was convincing that high degrees of eosinophilia in American soldiers usually indicated helminthic infections. On the basis of this premise, every case of unexplained eosinophilia was studied intensively. Recently, the records of these patients were reviewed. As a rule they were combat infantrymen hospitalized for vague but incapacitating intestinal complaints. Hookworm ova were found in the majority of cases,

and Strongyloides in some. In the latter, examination of duodenal fluid was the only method of diagnosis. The similarity of symptoms between the patients with helminthic infections and others previously studied with anxiety neuroses was striking.

MATERIAL AND METHODS

A large Army station hospital with thirty-six months' service in the South and Southwest Pacific theaters of operation had a substantial number of patients with high degrees of eosinophilia whose causes were not being determined by routine methods. During 1944-1945 in New Guinea, the medical and laboratory services established an "unexplained eosinophilia ward" to study patients in whom laboratory studies on the respective wards did not clarify the cause for eosinophilia.

Clinical studies. Histories in the form of questionnaires, with special reference to allergic diatheses, systemic complaints and exposure to parasitic infections, were utilized. Physical examinations were detailed and frequent. Special diets were available, and recreational facilities in the hospital were excellent for New Guinea.

Laboratory studies. Detailed analyses of the blood and urine were made. Diagnostic gastric and duodenal intubations, roentgenograms of the gastrointestinal tract, using contrasting mediums, and of other systems when indicated, and proctoscopies were performed routinely on the last 25 patients. Each fecal specimen passed during the first three days was studied for ova and parasites by a concentrated method.⁶ Thereafter, at weekly intervals, a dose of magnesium sulfate was administered, and all stools passed on that day were examined. The blood, urine, gastric and duodenal fluid and prostatic secretions were also examined for ova and parasites. An eosinophilia of 9 per cent or more was considered significant. Cutaneous testing materials for specific allergens were not available.

RESULTS

Fifty-nine patients with unexplained eosinophilia were studied. Forty-seven (79 per cent) were found to have intestinal helminthic infections. Of this group, 42 (89 per cent) had hookworm disease, whereas 5 (11 per cent) had strongyloidiasis. In the

‡The average duration of symptoms before hospitalization was two years.

12 other cases the cause for the eosinophilia could not be determined.

The findings in the three groups of patients described are presented in Tables 1 and 2.

Hookworm Disease

Of 42 patients with hookworm disease, 29 (69 per cent) were admitted with diagnoses referable to the gastrointestinal tract, including psychoneurosis, gastroenteritis, appendicitis, peptic ulcer, duodenitis, colitis and hookworm disease. In 2 cases the diagnosis on admission was acute rheumatoid arthritis, and 11 patients were hospitalized for con-

ditions not related to the helminthic infection. The patients were studied because eosinophilia was found on routine blood examination. Ten patients (25 per cent) of the entire group had previously been hospitalized with the same complaints.

The predominant symptom was abdominal distress, which most patients described as an intermittent, severe, cramplike pain in the epigastrium that usually occurred after eating and lasted a few hours. The pain was more intense at night and was not relieved by food, alkalies or defecation. Others complained of dull, aching sensations in the periumbilical region, and a few had inconstant pains in the midabdominal area that radiated to the chest or back. Some patients were disturbed by constipation alternating with soft, mushy movements, although in the majority of cases the bowel habits were normal. Almost all patients emphasized anorexia, nausea, weakness, fatigue, weight loss, vomiting and nervousness. Less frequent complaints were headache, palpitations, tremors and night mares. Physical examinations were not helpful.

The majority of patients had been sufficiently exposed during combat patrols to acquire hookworm disease. Usually, they had slept on the ground, swum in streams near native villages or eaten unpackaged bread dropped from parachutes. On the average, the onset of symptoms after probable exposure was one hundred and forty-three days, and one hundred and thirty additional days elapsed before symptoms became severe enough to warrant hospitalization. Ordinarily a patient was hospitalized twenty-one days before he was transferred to the ward for study, and the diagnosis was most frequently made during that period.

The average red-cell count was 4,300,000, with a hemoglobin of 87 per cent (Sahli). As a rule, there was a slight leukocytosis, although the eosinophil count was high (9 to 36 per cent). Such high counts were usually found on admission and persisted after discharge. Ova of *Necator americanus* were often found in the feces during the third week of study. Other laboratory findings were irrelevant.

Thirty-three patients received tetrachlorethylene in the prescribed manner.⁷ The results of treatment were considered successful in 28 cases, although symptoms in a milder form usually persisted and ova were occasionally found. In the other cases neither the symptoms nor the parasites seemed affected, in spite of several courses of anthelmintic therapy. Nine patients treated with carbon tetrachloride responded in a like manner.

The following cases were typical of the group with hookworm disease.

CASE 1. A 30-year-old combat infantryman was admitted to the hospital because of headache, dizziness and nausea of 1 week's duration. On the day before admission he had struck his head accidentally. The admission tag stated, "Discharge quickly—patient is neurotic, with fixations of pain in head and stomach."

30 months before admission, the patient first complained of "headaches" followed by sharp, knifelike pain in the epigastrium occurring daily in the late afternoon and persisting until morning. Nausea was frequent, but vomiting rare. Neither food nor alkalies relieved the pain. During the following month he became irritable, discontented and nervous. He attended sick call frequently, but medication did not help. The accident precipitated admission to the hospital.

Physical examination was essentially negative. Laboratory studies revealed an eosinophil count of 14 per cent. Three stool examinations (concentrated method) were negative.

The patient was transferred for further study to the "eosinophilia ward," where the past history was found to be contributory. He had been in the combat zone in New Guinea for 1 year prior to the onset of symptoms, but denied breach of sanitary precautions. Laboratory studies over a period of 3 weeks were negative, these included several stool examinations and two duodenal intubations. The patient

was ministered. The patient recovered but during the week developed a mild diarrhea. Concomitantly a leukocytosis and an eosinophil count of 11 per cent were found. A stool examination was negative, and the diarrhea receded without specific therapy.

Two weeks later the patient complained of nausea, anorexia and abdominal distress. He was transferred to the hospital with a diagnosis of psychoneurosis. On arrival he was irrational and had hyperactive reflexes. A diagnosis of hysteria was made.

Six weeks later the patient was transferred to the "eosinophilia ward." Questioning revealed that in 1942 he had been hospitalized for a fractured skull. Within the following 6 months he had had two convulsions and several violent temper tantrums. He had been inducted into the Army in January, 1943. In August, while on maneuvers, he had had urticaria and hay fever. En route to New Guinea in May, 1944, he had been operated on for appendicitis. During combat patrols in October 1944, he had swum in fresh-water streams and eaten native food. He had been sent to rest

was treated with iron and vitamins and returned to duty, because the symptoms had improved.

Three days later, he was readmitted with severe epigastric distress. Physical examination revealed some spasm and tenderness over the right rectus muscle, but this receded promptly after an enema. Eosinophilia was still present. A second gastrointestinal series and two stool specimens examined a week apart were normal. During the 3rd week, ova of *N. americanus* were found in the feces. Treatment was instituted. The symptoms subsided and the patient returned to duty within 3 weeks.

In this case a diagnosis of hookworm disease was made seven weeks after a careful study had been initiated, and four months after the onset of abdominal complaints. This case illustrates that a long period of observation may be necessary before a diagnosis of hookworm disease can be established.

CASE 2 A 22-year-old infantryman was admitted from combat to a field hospital with bronchopneumonia. X-ray examination confirmed the diagnosis, and penicillin was ad-

ministered on several occasions but had returned to actual combat of his own volition.

The patient was admitted to the study ward during February, 1945. Physical examination revealed a sullen, uncooperative soldier, who showed evidence of marked weight loss. Laboratory studies revealed a white-cell count of 25,500, with 24 per cent eosinophils. Five stool examinations were negative. A positive diagnosis of hookworm disease was made during the following week. Satisfactory recovery was made after two courses of an anthelmintic.

This case illustrates the difficulties of differentiation. The entire syndrome could have been helminthic in origin, but in view of the previous neuropsychiatric disturbance, it seemed more plausible that the helminthic infection merely precipitated a severe emotional upset.

Strongyloidiasis

The 5 patients with strongyloidiasis were admitted with the following diagnosis "Psycho-

Hookworm Disease

Of 42 patients with hookworm disease, 29 (69 per cent) were admitted with diagnoses referable to the gastrointestinal tract, including psychoneurosis, gastroenteritis, appendicitis, peptic ulcer, duodenitis, colitis and hookworm disease. In 2 cases the diagnosis on admission was acute rheumatoid arthritis, and 11 patients were hospitalized for con-

ditions not related to the helminthic infection. The patients were studied because eosinophilia was found on routine blood examination. Ten patients (25 per cent) of the entire group had previously been hospitalized with the same complaints.

The predominant symptom was abdominal distress, which most patients described as an intermittent, severe, cramplike pain in the epigastrium that usually occurred after eating and lasted a few hours. The pain was more intense at night and was not relieved by food, alkalies or defecation. Other complaints of dull, aching sensations in the periumbilical region, and a few had inconstant pains in the midabdominal area that radiated to the chest or back. Some patients were disturbed by constipation alternating with soft, mushy movements, although in the majority of cases the bowel habits were normal. Almost all patients emphasized anorexia, nausea, weakness, fatigue, weight loss, vomiting and nervousness. Less frequent complaints were headache, palpitations, tremors and nightmares. Physical examinations were not helpful.

The majority of patients had been sufficiently exposed during combat patrols to acquire hookworm disease. Usually, they had slept on the ground, swum in streams near native villages or eaten unpackaged bread dropped from parachutes. On the average, the onset of symptoms after probable exposure was one hundred and forty-three days, and one hundred and thirty additional days elapsed before symptoms became severe enough to warrant hospitalization. Ordinarily a patient was hospitalized twenty-one days before he was transferred to the ward for study, and the diagnosis was most frequently made during that period.

The average red-cell count was 4,300,000, with a hemoglobin of 87 per cent (Sahli). As a rule, there was a slight leukocytosis, although the eosinophil count was high (9 to 36 per cent). Such high counts were usually found on admission and persisted after discharge. Ova of *Necator americanus* were often found in the feces during the third week of study. Other laboratory findings were irrelevant.

Thirty-three patients received tetrachlorethylene in the prescribed manner.⁷ The results of treatment were considered successful in 28 cases, although symptoms in a milder form usually persisted and ova were occasionally found. In the other cases neither the symptoms nor the parasites seemed affected, in spite of several courses of anthelmintic therapy. Nine patients treated with carbon tetrachloride responded in a like manner.

The following cases were typical of the group with hookworm disease.

CASE 1. A 30-year-old combat infantryman was admitted to the hospital because of headache, dizziness and nausea of 1 week's duration. On the day before admission he had struck his head accidentally. The admission tag stated, "Discharge quickly — patient is neurotic, with fixations of pain in head and stomach."

poison ivy. During combat patrol, in August, 1944, he had bloody dysentery. Laboratory studies revealed an eosinophil count of 32 per cent, and two examinations of the duodenal fluid revealed a marked epithelial exudate associated with neutrophilic and eosinophilic polymorphonuclear leukocytes. No ova or parasites were found. The patient was treated with iron and vitamins. The symptoms improved, and the eosinophil count receded to 12 per cent. He returned to duty 3 months later, when he was somewhat recovered.

This case represents a diagnostic problem. The patient had always lived in a region where hookworm is endemic, he had a history of allergy, as well as gastrointestinal symptoms, that predated tropical climate, and was convalescing from infectious hepatitis. Clinically, this patient resembled those in cases of strongyloidiasis, and the duodenal fluid simulated the fluid of patients with that finding. Yet, the absence of larvae, this finding is of questionable significance.

CASE 6 A 20-year-old noncombatant soldier was admitted to the hospital with a diagnosis of "generalized myositis." He complained of a stiff neck and aching legs of 2 months' duration. Physical examination revealed a thin, asthenic man, who held his head stiffly to one side. The right sternocleidomastoid muscle was spastic and tender to palpation. Laboratory studies were essentially negative except for an eosinophil count of 28 per cent.

The patient was transferred to the study ward. He had been born and had lived on a farm in Missouri. Ever since childhood the legs had ached and the joints had occasionally been stiff. Since induction into the Army he had complained of fatigue on several occasions, and during his overseas service had been hospitalized with that complaint three times in 3 months. Roentgenograms of the muscles were negative for calcifications. An elevated blood ureic acid was found on two occasions, but other laboratory studies were negative. The eosinophil count receded to 11 per cent without specific treatment. The patient was returned to the United States unimproved.

Simultaneous tests for specific allergins, especially tests for trichina, might have clarified the diagnosis in this case. Clinically, the patient had rheumatoid arthritis. He could not be classified as having hookworm disease or strongyloidiasis.

DISCUSSION

Hookworm disease acquired in the Southwest Pacific differs materially from the disease as it is known in the southern United States. It seems likely that the symptoms reflect allergic or invasive phenomena rather than anemia, which is often responsible for the classic manifestations. The fact that it was frequently impossible to find ova in the feces during a period when the symptoms were most distressing strengthens this impression. Allen⁸ reported that eosinophilia was present in soldiers long before hookworm ova could be found. Eggs were found, however, when the patients were studied long enough. This was also observed in the majority of the cases discussed herein.

Chacon⁹ described early symptoms of ankylostomiasis in Porto Ricans. Violent headaches and dizziness were most frequent initial complaints. Pain in the knees and waist, fatigue, sleepiness and palpitation appeared early in the disease. Three other symptoms were consistently present: epigastric

gastric pain, — as well as a feeling of fullness after meals, — mild diarrhea and "watering of the mouth." Soldiers in New Guinea had comparable complaints. Recently, Rogers and Dammin¹⁰ reported a syndrome occurring in American soldiers stationed in Assam and Burma characterized by acute gastrointestinal symptoms, severe diarrhea and eosinophilia. No difficulty in finding hookworm ova in the feces was encountered, however, when specimens were prepared by a flotation centrifugation method. In addition, gastrointestinal roentgenograms showed peculiar cogwheel abnormalities of the small intestine. It appears that the cases discussed above and those reported by Allen represented minimal infestations, whereas those reported by Rogers and Dammin indicated either a heavier parasitemia or an extreme response to the allergin.

Eosinophilia is a most important diagnostic lead in obscure parasitic infections. Although it must be interpreted as a nonspecific finding associated with a multiplicity of allergic diseases, an increasing eosinophilic leukocytosis usually indicates helminthic infection. Similarly, when high eosinophil counts (9 per cent or more) are consistently associated with dengue, scrub typhus, infectious hepatitis, malaria, the dermatoses and the allergic respiratory diseases, in which a value of 6 per cent is average, nematode infection should be suspected. Eosinophilia, which is usually present weeks before the parasite can be demonstrated, generally persists long after treatment has been considered adequate. In the absence of specific cutaneous tests for allergins, eosinophilia must be regarded seriously.

The patients with strongyloidiasis presented interesting diagnostic problems. They were shunted from hospital to hospital, being considered psychoneurotic. They remained on the wards for weeks, obviously ill, but without presenting any positive diagnostic criteria other than eosinophilia. Finally, when the duodenal fluid was examined, motile larvae were found without difficulty. Yet stool examinations repeatedly failed to reveal the larvae, even when they were known to be present in the duodenum. Perhaps, in minimal infections, the parasites are not irritating enough to cause diarrhea. It is usually in that type of stool that the larvae are found.

Duodenal intubation as a diagnostic method in strongyloidiasis has not been stressed sufficiently. It is not a difficult procedure,¹¹ but it takes time. Fluoroscopy speeds the operation but is not essential. Normally, the alkaline duodenal fluid is devoid of parasites, evidence of an inflammatory reaction or a significant amount of tissue debris. *N. americanus* and *S. stercorarius*, after they have completed their invasive cycle, settle in the small intestine, where their eggs are laid. In addition to fecundity, the worms are said to liberate toxins that cause disturbing nonspecific and gastrointestinal symptoms. Whereas hookworm ova hatch in the feces outside

neurosis manifested by vague abdominal complaints."

The general pattern of the complaints was similar to that in patients with hookworm disease. There was less specificity, however. Abdominal pain occurred at any time during the day or night, varying in intensity. Often, it was cramplike, it was more frequently described as an "ache that was always there." Other disturbing features were increasing weakness, irritability and nervousness. There was evidence of marked weight loss and asthenia.

Four patients gave adequate histories of possible exposure. The average onset of symptoms was twenty-four days after exposure, but another hundred days elapsed before the distress was severe enough to warrant hospitalization. The patients were hospitalized several months before examination of the duodenal fluid clarified the diagnosis.

The examination of concentrated specimens of duodenal fluid was diagnostic in every case. In 4 patients, motile, rhabditiform larvae of *Strongyloides stercoralis* were found only in the duodenal juice, whereas in 1 larva were also found later in a diarrheal stool. The appearance of the duodenal contents suggested chronic inflammation. There were large amounts of columnar epithelium and mucous shreds, as well as many round cells, neutrophils, eosinophils and erythrocytes. In 4 cases examinations of the feces were consistently negative.

Treatment consisted of 25 cc of a 1 per cent aqueous solution of gentian violet, administered intraduodenally. The symptoms persisted in spite of repeated treatment, although 1 patient improved temporarily. The following cases were characteristic.

CASE 3 A 28-year-old combat infantryman was admitted with the diagnosis of "psychoneurosis manifested by vague intestinal pains" in July, 1944. While on combat patrol, 7 weeks previously, he had been seized with severe aching cramps across the epigastrium. Nausea, vomiting and diarrhea were conspicuously absent. Because of recurrent attacks, the patient was admitted to a field hospital, where examination, including a gastrointestinal x-ray series with contrasting mediums, was negative. After 3 weeks he was evacuated to this hospital for psychiatric evaluation.

Physical examination showed the patient to be ill and emaciated, with a peculiar gray pallor. Routine studies were negative except for a moderate leukocytosis and an eosinophil count of 35 per cent.

The patient was transferred to the study ward, where questioning revealed that he had been in combat in the Solomon Islands in 1943, with no sequelae. While on combat patrol in New Guinea during the following summer, he had swum in a stream adjacent to a native village and had eaten native food and unpackaged bread dropped by parachute. Detailed laboratory studies during October and December, 1944, had been negative, as were many stool examinations. During the 3rd month of study the duodenal fluid was examined. On the first specimen 8 to 12 actively motile larvae within clear refractile shells (*S. stercoralis*) were found. A large number of columnar epithelial cells, mucous shreds, round cells and neutrophils and eosinophilic leukocytes were also observed. Specific treatment was initiated, with some relief in the following week. During the 3rd week the symptoms returned in a milder form. Duodenal intubation was repeated. Larvae were not found in the fluid, but a moderate amount of exudate was present. Treatment was repeated, but abdominal unrest persisted. The patient was returned to the United States for further study.

This case demonstrates that negative stool examinations cannot eliminate the possibility of helminthic infections. This patient was hospitalized much longer than usual, because the medical officer was impressed by his complaints. Duodenal intubation clarified the reason for the eosinophilia, and a diagnosis of psychoneurosis was averted. It is possible that a neurosis was acquired during the long period of hospitalization.

CASE 4 A 23-year-old combat infantryman was transferred from a field hospital with a diagnosis of "psychoneurosis manifested by vague abdominal complaints." During May, 1944, while on combat patrol, he had noticed constant needle-like pain in the right epigastrium that was temporarily relieved by food. At night, the pain was intense, but vomiting followed eating. The patient was hospitalized and treated with antispasmodics, returning to duty in 2 weeks. He was readmitted 2 months later because the symptoms were worse. During the interim he had lost 40 pounds of weight and had become extremely nervous. He was transferred to this hospital in September, 1944. Routine examinations were negative except for a moderate leukocytosis and an eosinophil count of 50 per cent.

The patient was transferred to the "eosinophilia ward." During combat in 1942, he had been hospitalized twice for projectile vomiting. Later, in Australia, a diagnosis of psychoneurosis was made. When he returned to combat in May, 1944, he admitted breaches in sanitary precautions.

Three months after readmission examination of the duodenal contents revealed a few actively motile rhabditiform larvae of *S. stercoralis* in each specimen. There was a large amount of epithelial debris and cellular exudate. Eosinophils were abundant. The symptoms persisted in spite of adequate therapy, although larvae were not found again. Evacuation to the United States seemed indicated.

This case also demonstrates the difficulty in differentiating neurotic complaints from symptoms caused by helminths. The past history suggested that the patient was neurotic. The high degree of eosinophilia, however, was a diagnostic lead, and proves that this finding is significant. Again, an unstable personality may explain why complete regression of symptoms was not achieved.

Eosinophilia of Undetermined Origin

In 12 cases no cause for the eosinophilia was found. The symptoms in 9 simulated those in the soldiers with helminthic diseases. All patients had a history of possible exposure, and many had previously been hospitalized for the same complaints. Three patients had histories of allergies and non-specific complaints that predated Army service.

Laboratory studies were negative, although the duodenal contents in 3 of 9 cases resembled those in which *S. stercoralis* had been found, except that larvae were absent.

CASE 5 A 22-year-old infantryman was admitted with a diagnosis of "psychoneurosis manifested by vague intestinal symptoms." The main difficulty was eructation of sour material after every meal. This symptom had begun in 1943, shortly before overseas assignment. In September, 1944 in New Guinea, the patient was hospitalized for gastritis and hepatitis. Because of the persistence of eructations and of a throbbing ache in the epigastrium, he was evacuated to this hospital. Physical examination was essentially negative, but laboratory studies revealed an eosinophil count of 36 per cent.

The patient was transferred to the study ward. He was a native of Mississippi. He had always been allergic to tomatoes.

MEDICAL PROGRESS

CANCER

GRANTLEY W TAYLOR, M.D.*

BOSTON

POSTWAR survey of practice and theory in relation to cancer problems shows little fundamental change in comparison with the prewar years, though in some fields there have been modifications and shifts in emphasis. This review can make pretense of being complete, but it seems desirable to comment on certain aspects of the problem.

Carcinoma of the Mouth

There appears to be an increasingly accurate dissemination regarding the respective fields of radiation and surgery in the treatment of primary intracranial carcinoma.^{1,2} The former division into separate camps, with exclusive use of radiation in some clinics and exclusive use of surgery for operable cases in others, has given place to a willingness to concede the value and merit of the other approach. This comes about through accurate critical analysis of the results achieved in cases of carefully defined location, extent and histology. Radical surgery is applicable primarily in small accessible tumors that are of a relatively low grade of malignancy. The more extensive high-grade lesions are better suited to radiation therapy. The results of this treatment have improved with the employment of greater dosage. There has also been clarification of the indications for neck dissection, as well as of the benefit that may be expected as a result of dissection.³

Carcinoma of the Larynx

Similar clarification is desirable in laryngeal carcinoma. Cutler⁴ has presented an impressive series of cases treated by a modified Coutard method of radiation. Schall⁵ and others have successfully employed laryngectomy in a large number of cases. It is probable that many of the patients treated by laryngectomy might have been cured by radiation. It is also possible that certain of the cases that proved to be refractory to radiation might have been successfully treated by laryngectomy. Analysis of the clinical and pathological characteristics that contribute to a successful outcome by one or another method of treatment should be carried out at every opportunity.

Mixed Salivary Tumors

In spite of the sustained interest of McFarland⁶ in the mixed salivary tumors, their origin and pos-

sible relation to the development of carcinoma remain obscure. In general, these tumors are smaller when the patients first seek advice than they were several years ago. Earlier textbooks describe the characteristic tumor as the size of a walnut, or even an egg. In recent experience, such large tumors are distinctly unusual in this community. The apparent tendency to evolve toward benignancy with increased duration and size, noted by McFarland, may be explained by the fact that the larger tumors are operated on with more respect and more radically. The propensity to recur following simple excision has led to increasing employment of the Adson-Ott operation⁷ in which the entire gland superficial to the facial nerve is resected, including the tumor. The excellent anatomical studies of this region by McCormack et al.⁸ should be reviewed by all surgeons who undertake to perform this operation.

Carcinoma of the Thyroid Gland

There is general agreement that thyroid carcinoma usually originates in a pre-existing pathologic condition of the gland, frequently in a solitary nontoxic nodule. In fact, the incidence of carcinoma in solitary nontoxic nodules may be as high as 24 per cent,⁹ or even higher.¹⁰ There is general acceptance of invasiveness and blood-vessel invasion as criteria of malignancy. The problem at once arises concerning how much further surgery may be necessary when the pathologist unexpectedly returns a report of carcinoma in an apparently innocent nodule that has been removed at operation.

The high incidence of carcinoma in these nodules argues that excision be abandoned. Wide resection of the involved area or complete excision of the lobe should be carried out. This procedure is probably sufficiently radical when there is no clinical evidence of malignancy and when there is no pathological evidence of invasion of the gland capsule. When malignancy is suspected or when there is evidence of invasion of the gland capsule at operation, it is essential to carry out block dissection of the affected side. This involves removal of the sternomastoid, sternohyoid, omohyoid and sternothyroid muscles, the internal jugular vein from the junction with the subclavian vein to the lower pole of the parotid gland and the lymphoid tissue and fat from the anterior border of the trapezius muscle to the midline.

*Associate in surgery Harvard Medical School, visiting surgeon, Massachusetts General Hospital, visiting surgeon, Pondville State Cancer Hospital.

the body, the eggs of *Strongyloides* hatch in the small intestine, causing a catarrhal inflammation characterized by a round-cell and eosinophilic exudate^{12, 13} Usually, a persistent diarrhea results in which free motile rhabditiform larvae may be found.

An eosinophilic exudate has been observed in the duodenal fluid in strongyloidiasis but not in that from patients suffering from hookworm disease. Neither the hookworm adult nor ova could be found in the duodenum even at a period when it was not yet found in the feces. In some cases in which eosinophilia remained unexplained, the duodenal fluid suggested an allergic exudate. The significance of inflammatory reactions, however, as portrayed by the duodenal juices, must be regarded with caution, because comparable exudates have been observed following the ingestion of magnesium sulfate.¹⁴

During this hospital's period of service a substantial number of cases were diagnosed as psychoneurosis. A significant number with the syndrome described in this paper fell into that category. Their symptoms may have been essentially helminthic in origin, but on the other hand, the conditions of jungle warfare may have been responsible for the display of neurotic tendencies. Certainly, long periods of medical treatment without relief or even proper diagnosis contributed to puzzling complaints. The consensus was that these patients were neurotic regardless of their infections. Because treatment was unsatisfactory, as manifested by the persistence of ova or larvae and eosinophilia after adequate anthelmintic therapy, perhaps a definite opinion of the mental reactions should be held in abeyance until additional reports of the early manifestations of helminthic diseases are collected.

Certain criteria that Rush³ established in a group of patients with anxiety neurosis studied in this hospital help differentiate the true psychoneurotic patients from those with pathologic findings to account for their complaints. The symptoms manifested by Rush's group hardly differed from those in patients with helminthic disease, and yet the type of patient differed. The true neurotic patient had been in the tropics only a short time before he was hospitalized, he was never in combat because he was "always weeded out", his chief complaint was abdominal pain, which was frequently relieved after defecation, he overaccentuated any single complaint, and this varied from day to day, he showed no evidence of weight loss or malnutrition, and, finally, intestinal parasites were never found, nor was there an eosinophilia. On the other hand, patients with proved or suspected helminthic diseases, who seemed of a different temperament, were consistent in their complaints. Positive or suggestive laboratory findings were always present.

Prior to this study, the causes were found in approximately 40 per cent of soldiers with eosinophilia admitted to the hospital. With special efforts, the reasons for eosinophilia in the majority of cases were

clarified. It was gratifying that a diagnosis of psychoneurosis was deferred in a substantial number. Although neurotic tendencies were outstanding in many of the patients studied, evidence is being accrued that the early symptoms of helminthic infections were different from those that were expected.

SUMMARY

Fifty-nine American soldiers hospitalized in New Guinea were studied for unexplained eosinophilia. Forty-seven (79 per cent) were found to have intestinal helminthic infections. Forty-two (71 per cent) had hookworm disease, 5 (8 per cent) had strongyloidiasis and 12 (20 per cent) presented no demonstrable cause for the eosinophilia.

The majority of patients were admitted to the hospital because of abdominal complaints. A substantial number were classified as psychoneurotic prior to study. The predominant symptom was intermittent, cramplike epigastric pain. Anorexia, nausea, vomiting, weakness, fatigue, nervousness and weight loss were prominent. Physical examination was negative.

The onset of symptoms usually occurred four and a half months after probable exposure, and the symptoms became severe enough to warrant hospitalization during the next four and a half months.

Laboratory studies revealed a persistently high eosinophil count (9 per cent or more). In patients with hookworm disease, ova were found in the feces, usually during the third week of the study. Examination of duodenal fluid was the only method of diagnosing 4 of 5 cases of *Strongyloides* infection. In these patients, larvae were not found in the feces.

The diagnosis of psychoneurosis may not be warranted in the veteran with the syndrome described in this report.

is has been given to this trend by the anatomical lies of the lymphatic drainage areas carried out Dukes,³² Grinnell,³³ Kay³⁴ and others. Their findings establish that downward lymphatic spread in rectal cancer is rare and only likely to occur in the upward-draining lymphatic vessels are clogged by cancer metastases. These conservative operations are technically difficult and probably no so sound as the more orthodox procedures from the point of view of a thorough operation. The likelihood of postoperative complications appears to be greater, and the prospect of adequate function of the preserved sphincter is problematical. In addition, whereas the procedures perhaps fulfill the requirement so far as lymph-node involvement is concerned, they appear to disregard the fact of venous involvement, which is increasingly recognized as significant.

An important study of carcinoma of the rectum on a state-wide basis has recently been presented by Ottenheimer,³⁵ who reports the experience in Connecticut. The value of such a survey cannot be overemphasized. It serves both to define the problem and to provide a base line against which progress can be measured. Although other states may plead the increased difficulties of such surveys in a heterogeneous population, the value of this approach to cancer of various regions is obvious. It is to be hoped that further studies on other groups will be carried out.

Carcinoma of the Cervix

The Papanicolaou³⁶ test for cancerous cells in the vaginal smears has been hailed with some enthusiasm as a method of screening patients to find carcinoma of the uterus in a presymptomatic stage. In the hands of competent interpreters of the slides it may achieve a high degree of accuracy. The method has been applied to other secretions, such as sputums, gastric washings and the contents of cysts. It may prove to be a useful adjunct to diagnostic procedures. It is probably too protracted and too dependent on expert interpretation for use as a routine screening procedure on a large completely asymptomatic group of patients.

Meigs³⁷ has continued his series of Wertheim operations in selected cases of carcinoma of the cervix. In the cervix, as in the larynx, radical surgery in selected cases yields excellent results. Radical radiation is also extremely effective, especially in early cases, whereas the selection of cases is not nearly so exacting. Here, as in the larynx, certain cases are refractory to radiation, and it is desirable to attempt more accurate identification of this refractory group. Taussig's³⁸ operation of iliac lymphadenectomy — a retroperitoneal dissection of the lymph-node areas — was designed to take care of lymph-node metastases following destruction of the primary cancer by radiation. Taussig found involved nodes in about 40 per cent of the patients sub-

mitted to the operation, in whom he obtained cures in about 25 per cent. Recently, Nathanson³⁹ accomplished the same objective by means of a retroperitoneal dissection through bilateral incisions in the groins.

Lymphoblastoma

The definitive classification of the lymphoblastomas was presented by Jackson and Parker.⁴⁰ Formerly, the terminology had been confusing, and it was often difficult to decide which group of tumors was under discussion in studies from various clinics. The work of Jackson and Parker, with its wealth of pathological material correlated with clinical progress, should lay the groundwork for appropriate therapeutic efforts.

Bone Tumors

In recent years, the clinician concerned with the diagnosis of bone disease has had to learn to recognize osteoid osteoma⁴¹ and eosinophilic granuloma.⁴² Although neither of these tumors is a true neoplasm, their occurrence and identification has probably added another difficulty to an already confusing problem. Fortunately, both lesions are benign and respond readily to appropriate surgical measures.

Carcinoma of the Prostate

Although Huggins⁴³ first reported his experiences in the treatment of carcinoma of the prostate by orchiectomy and estrogens several years ago, the literature still contains reports of successes, and there is some question regarding the duration of the remissions and the types of the disease likeliest to respond favorably. It is probable that several more years will elapse before final appraisal of this undoubtedly valuable adjunct of treatment.

Radiation Therapy

Holmes and Schulz⁴⁴ have published the results of million-volt x-ray therapy. They found less skin damage from the dose delivered to the tumor than with lower voltages. The results of treatment appear to be superior in carcinoma of the bladder,⁴⁵ cervix, lung and tonsil.

Miscellaneous

Pack and Ehrlich⁴⁶ published techniques as well as a series of cases of radical amputations, including the shoulder girdle, hip joint and sacroiliac. These mutilating procedures are occasionally indicated in extensive malignant processes, and as the authors point out, they may be indicated for palliation in some cases.

The criteria of malignancy have already been referred to in the discussion of thyroid carcinoma. The clinician is too ready to accept as fact the diagnosis offered by the pathologist without recognizing that such a diagnosis is a conclusion and judgment based on an assembly of data. One is occasionally

Thus, the operation is essentially a radical neck dissection except that the submaxillary area need not be included. The likelihood of lymph-node metastasis as the sole or earliest manifestation of spread is great, especially in the relatively low-grade papillary adenocarcinomas.

Lahey¹¹ has again emphasized the likelihood of the development of malignant changes in aberrant thyroid nodules. It must be recognized that some tumors of this sort may be metastases from undetected primary foci of disease in the thyroid gland itself.

The use of thiouracil in the treatment of hyperthyroidism involves some consideration of its possible relation to carcinogenesis in the gland. Bielschowsky¹² reported the development of cancer of the thyroid gland in experimental animals by the use of a carcinogen, 2-acetyl-amino-fluorene, in conjunction with allyl-thiourea. Neither compound alone was capable of producing thyroid carcinoma in control animals.

Carcinoma of the Breast

Foote and Stewart¹³ have made a major contribution to the pathology of benign breast conditions and their relation to carcinoma. Haagensen and Stout¹⁴ reported an exhaustive analysis of their experience with carcinoma of the breast, especially analyzing the prognostic significance of certain clinical manifestations of the disease. Their experience was closely paralleled by that of Wells¹⁵ and, indeed, coincides with that of most other clinics where a considerable number of these patients are treated. Variations in the criteria of operability probably account for variations in results. The use of estrogens in the treatment of advanced carcinoma of the breast, especially in patients beyond the age of sixty, promises to be a valuable palliative procedure in some cases.^{16, 17} It is too early to discover how long the regressions may be maintained. The use of testosterone has also brought about regressions in certain cases.¹⁸

Carcinoma of the Lung

Tremendous strides have been made in recent years in the technics of thoracic surgery, and significant series of radical operations for lung carcinoma are now recorded. Lindskog¹⁹ called attention to the low operability rate for radical procedure and the advanced stage of disease presented by most patients when first seen. Mass screening by chest x-ray examination, which has successfully been carried out for tuberculosis, might be applied to a large group in an attempt to find cancer of the lung in a presymptomatic and favorable stage. Herbut and Clerf²⁰ have applied the Papanicolaou method of examination to sputums, with encouraging results.

Carcinoma of the Esophagus

In no field has the development of thoracic surgery led to such rapid progress as in the problem of carcinoma of the esophagus and of the cardiac end of the stomach. Sweet²¹ has reported a brilliant series of esophageal resections, with a constantly diminishing mortality. It is discouraging to discover that lymph-node metastases are frequent, occurring early, and that attempts to include many of them in the resection are not successful. Even as a palliative procedure, however, the operation is highly successful. A similar approach and technique give excellent access to carcinomas at the cardiac end of the stomach, in which the results are also promising.²²

Carcinoma of the Stomach

As in carcinoma of the lung, a discouraging picture applies to carcinoma of the stomach in the fact that operability rates for radical excision remain relatively low. Wangenstein²³ and his co-workers undertook screening by gastric analysis, followed by further investigation of the achlorhydric patients. In this fashion they found a significant number of patients with gastric polyps, which are often conceded to be precancerous. Various authors^{24, 25} have extended the indications for radical surgery in most abdominal carcinomas to include a large group with fixation to adjacent organs and with metastases in the liver and spleen. Although these operations are a challenge to surgical skill and to the restorative and antishock efforts of the team, it is doubtful whether much good is accomplished, even as palliation.

Carcinoma of the Pancreas

The development of the Whipple²⁶ operation and its various modifications have made it possible to attack carcinomas of the pancreas,²⁷ duodenum and bile ducts²⁸ with greater assurance, lessened operative mortality and an increased likelihood of success. These advances are due not only to technical progress but also to improved understanding of maintenance of physiologic equilibrium.

Carcinoma of the Colon and Rectum

In recent years a revived employment of open resections in the colon has been made possible in part by improvements in technic and in part by the use of decompression as a safeguard, as well as by the use of chemotherapeutic agents, especially sulfa-thalidine and succinylsulfathiazole (Sulfasuxidine). The increased safety of open resections has led to revival of procedures to preserve the anal sphincter and to avoid a permanent colostomy in dealing with growths that are low in the colon.²⁹⁻³¹ Some of

CASE 33061

PRESENTATION OF CASE

First admission A forty-three-year-old automobile aler was admitted to the hospital because of chest in

On the previous day the patient had suddenly en seized with pain beneath the sternum and upper ick, noted especially on deep breathing. The pain rsisted, growing worse when he was lying down, id kept him awake for a time, although he felt etter on the following day. Work intensified the ain, especially when he stooped. He visited a ysician, who found no fever, hoarseness or pharyn- eal congestion, but because of a white-cell count of 3,000 he was referred to the hospital.

The patient had had two gonorrheal infections he second one occurring three years previously both had cleared with therapy. He smoked con- tantly and took small amounts of alcoholic drinks egularly.

Physical examination revealed that the heart was ot enlarged and that the sounds were of good qual- ty. Nothing else of note was found.

The pulse was 110, and the blood pressure 150 systolic, 90 diastolic.

Examination of the blood showed white-cell counts of 9000 and 12,500, with normal differential counts. The urine was normal. X-ray examination of the chest was negative. An electrocardiogram dis- closed rather low QRS complexes in Leads 1, 2 and 3 but normal ST segments and T waves in all four leads. The patient was discharged two days after admission.

Second admission (two years later) The patient had had no further symptoms since the previous ad- mission until he was again admitted for chest pain. About 1 00 a m on the day before admission the patient awoke with an aching substernal pain pen- etrating to the back and spreading to both shoulders and down both arms. He arose and stayed up the rest of the night. The pain lessened during the next day but persisted beneath the xiphoid and extended to the throat. Lying on the back eased it only slightly and sitting up or lying on either side made it worse.

Physical examination revealed a split aortic second sound along the left sternal border but no enlarge- ment of the heart or other abnormalities.

The temperature was 100°F.

Examination of the blood disclosed a white-cell count of 21,900, with 95 per cent neutrophils, with a shift to the left. The hemoglobin was 16.5 gm. The urine was normal except for a ++ test for al- bumin and 150 white cells per high-power field in the sediment. An x-ray film of the chest revealed a moderately enlarged heart with prominence in the region of the left ventricle. Fluoroscopically the pulsations were weak. The aorta was somewhat tortuous, without evidence of dilatation. The lung fields were clear except for a small area of increased density in the right base. A barium swallow showed a small hiatus hernia. An electrocardiogram revealed normal rhythm and a rate of 95. There was high origin of the T waves in Lead 1, with moderate late inversion, a flat T₂ and a diphasic T₃. The QRS complexes were low in the limb leads, and the pre- cordial leads showed an absent upright R wave in Leads CF₂ and CF₄, with high origin of the ST in- tervals in Leads CF₂ and CF₄, and late inversion of the T waves.

By the second hospital day the pain had dis- appeared and did not recur even on deep inspiration. Examination of the blood showed a white-cell count of 13,200. A gastrointestinal series revealed redun- dancy of the duodenum between the first and second portions. An electrocardiogram four days after ad- mission showed a slight change in the appearance of the ST intervals. ST₁ appeared more elevated, and T₁ was definitely inverted. ST₂ was more depressed, and in the precordial leads there was more elevation of the ST intervals and less late inversion. After two weeks the patient was transferred to a convalescent hospital, where he remained for three weeks.

Final admission (four months later) The patient returned to the hospital because of recurrent pain in the chest. Following discharge he had restricted his activity for a while and had then gone for short walks. He was able to climb three flights of stairs without difficulty, and during the third week he tried a short period of work at the office. That night, however, he had a severe attack of precordial pain radiating to both arms and to the back. He was seen by a physician, who observed a blood pressure of 150 systolic, 100 diastolic, and an apical gallop rhytm. The pain lasted for two days, and the patient remained in bed until a week before admis- sion, when he was allowed to sit in a chair. He occa- sionally developed some swelling of the ankles while sitting up. At 4 00 a m on the day of admission he had another attack of substernal pain, without radiation, but exaggerated on deep breathing.

Physical examination showed the patient to be in moderate discomfort, with steady substernal pain. The heart was moderately enlarged. The pulse was 96, with multiple extrasystoles. Crackling rales were heard at the left base, and the neck veins were prominent. The blood pressure was 104 systolic, 74 diastolic.

confronted with tumors whose clinical behavior is at variance with their histologic character. It is for this reason that great interest centers on the work of Greene and Lund,⁴⁷ who succeeded in growing human malignant tumors in the anterior chamber of the guinea-pig eye. This capacity for growth is apparently not shared by benign tumors, and the procedure may prove of value in determining the nature of a tumor in which the histologic character is obscure or equivocal.

gesting that the use of anticoagulants in patients who are having recurrent episodes of coronary thrombosis inhibits to some extent the formation of further coronary thrombi. I should be less hopeful, perhaps, about preventing these recurring episodes by this form of therapy than of lessening the chances of complications. In this connection, a report last summer in the *Journal of the American Medical Association*² recorded a series of 110 cases of acute myocardial infarction, 60 of these patients were used as controls and 50 were given anticoagulant therapy in the form of dicumarol. Of the control group 16 per cent developed clinically manifest peripheral emboli, and only 2 per cent of the treated group developed clinical embolism. That is a significant difference. Furthermore the deaths in the treated group were much fewer than those in the untreated group. This problem obviously requires extensive study and observation, preferably by more than one clinic or one group. Therefore, the American Heart Association has embarked on a project to study a large number of cases in several clinics under a controlled program so that each investigator will more or less follow the same scheme. The present arrangement is to treat alternate cases of acute myocardial infarction with anticoagulant therapy, such a program is now in progress in this hospital, as well as in several large hospitals elsewhere in this country. The answer remains to be seen.

What are the possible disadvantages of this therapy? A large mural thrombus might serve as a slow-out patch to prevent actual rupture of the heart. If the stoutness or extent of the thrombus is lessened, more cases of rupture of the heart may theoretically be expected. Perhaps Dr Mallory will express an opinion on that score. Furthermore, I have discussed with the surgeons what their reaction would be to a patient in whom, in spite of dicumarol therapy, a femoral artery suddenly occluded. Would they hesitate to do an embolectomy? They have not yet encountered this situation, but operation would not be contraindicated in spite of a prothrombin time between 35 and 50 seconds, which is the effective therapeutic level. There is one further probable indication for anticoagulant therapy in acute myocardial infarction: irritability of the heart with paroxysms of auricular fibrillation which, as is well known, is prone to result in thrombosis in the auricle and embolism peripherally.

In conclusion, it seems that this case afforded an ideal situation for this new and special form of therapy. We believe that it is reasonably safe. Before Dr Mallory tells us the post-mortem findings, I think that the clinical record should be clear. It is implied but not definitely stated that the patient was kept on dicumarol up to the time of death.

DR JAMES H. CURRENS That is correct.

DR BLAND We therefore have an opportunity in this case to see what thrombotic phenomena were

present after a patient had been on dicumarol for three months. I know of one patient kept on anticoagulant therapy for a period of six months without untoward effects.

DR JAMES H. TOWNSEND Would you predict where the various infarcts were?

DR BLAND That would lead us into a somewhat detailed discussion in this case.

DR TOWNSEND Which one occurred in which of these admissions?

DR BLAND In the second episode the electrocardiogram, as I have previously stated, was characteristic of an infarct in the region of the apex. The subsequent changes in the electrocardiogram with the third episode were rather noncommittal, suggesting further injury in the same region, or perhaps the electrocardiogram was modified either by the use of digitalis or by an infarct at the base. I should prefer not to go into great detail on that point. I think that the major infarct was at the cardiac apex. I should not be surprised if there were multiple infarcts in the heart, some large and some small, or if autopsy showed some old scars in the lung, possibly healed pulmonary infarcts.

DR BENJAMIN CASTLEMAN What do you think was the cause of death?

DR BLAND The patient died suddenly, as many patients with severe coronary disease do. I wondered perhaps if the heart had ruptured at the end. If it did, one must presuppose a fresh myocardial infarct, because healed infarcts do not rupture. The only clue was the two-week period of angina pectoris near the end, which may have represented further softening in the myocardium. In most people who die suddenly with coronary disease, however, we find simply marked coronary narrowing with areas of old infarction and occasionally a tiny fresh clot in one of the chronically obstructed coronaries, but usually not enough time elapses for microscopical or gross infarction to become evident. Many patients in the presence of marked coronary disease succumb suddenly, and we are unable to determine any specific additional cause of death at that particular moment. Perhaps it is cardiac standstill or ventricular fibrillation. Was quinidine given to this patient?

DR CURRENS No.

DR BLAND Was digitalis given?

DR CURRENS I believe that it was.

DR BLAND I shall be surprised if Dr Mallory says that the patient had a ruptured heart. I suspect that no specific cause for the final exitus, other than extensive coronary disease, was found.

DR CASTLEMAN In the new project, how long is a patient kept on anticoagulant therapy?

DR BLAND Six weeks. This project has just started. I do not know the laboratory details. Only one patient has been treated, and he died on the

Examination of the blood revealed a hemoglobin of 14.5 gm and a white-cell count of 20,400, with 84 per cent neutrophils and a shift to young forms. The urine showed a + test for albumin, and the sediment contained 20 white cells per high-power field. An electrocardiogram showed normal rhythm at a rate of 100, interrupted by ventricular premature beats. The QRS complexes were low in the limb leads. The T waves were flat in Lead I and low but diphasic in Leads 2 and 3, the PR interval was 0.18 second. The precordial leads showed inverted QRS complexes in Leads CF₁ and CF₂, with upright T waves and a flat T wave in Lead CF₄.

Anticoagulant therapy with dicumarol was instituted, and the prothrombin time was maintained at an average of approximately 40 seconds, with a control of about 18 seconds. The patient showed improvement during the first ten days of hospitalization, but subsequent electrocardiograms revealed slightly higher voltage in the limb leads and more inverted T waves in Leads I and CF₁. On the morning of the twenty-first hospital day, as on previous mornings, he complained of a sensation of "fluttering" and of "water" rushing through the precordial region but no pain. On physical examination the rhythm was grossly irregular, characteristic of fibrillation, but this changed shortly to a normal sinus rhythm, with frequent extrasystoles every third to fifth beat. The rate was about 92. He was discharged on that day.

The patient continued to take dicumarol, with frequent checks of the prothrombin time, which maintained an average of 40 to 50 seconds. After several weeks of rest in bed he gradually resumed physical activity and even returned to his office part time, but found it increasingly difficult to adapt himself to the disease. He became depressed, began to drink liquor freely, and had mild anginal attacks for two weeks. He died suddenly about three months after discharge.

DIFFERENTIAL DIAGNOSIS

DR EDWARD F. BLAND: We need spend little time in the discussion of the differential diagnosis, since it is obvious that the relatively new method of treatment employed in this case is the point of chief interest. Attention might be called, however, to the first episode of pain at the age of forty-three. The diagnosis in that attack from the clinical description is a little uncertain. The trouble was most probably of coronary origin, it could have been a pulmonary infarct. The pain was steady, and breathing caused discomfort. It is slightly unusual for the pain of a myocardial infarct to be sharply accentuated by breathing. That observation usually points to the lung, pleura or pericardium. There was no proof of a pulmonary infarct by x-ray examination or of a myocardial infarct on the electrocardiograms. The clinicians apparently did not consider this a serious illness, because the patient was per-

mitted to return home the next day. The subsequent course supported their decision, because there was no further trouble for two years.

The second episode, at the age of forty-five, was clearly, I believe, a coronary occlusion. The character of the pain radiating down both arms and the characteristic findings in the electrocardiogram pointing to a myocardial infarct at the apex of the heart leave little doubt regarding the diagnosis. The fact that the blood pressure did not drop need not be considered because when patients are seen during the course of coronary thrombosis — if they are having pain and if vascular shock has not occurred — the pressure is likelier to be elevated than the reverse. Furthermore, there was some enlargement of the heart. The statement in the x-ray report of slight density at the right base raises the possibility of a complicating pulmonary infarct. I shall ask Dr. Schatzki about that later.

DR RICHARD SCHATZKI: There are no x-ray films.

DR BLAND: We might proceed then to the third episode of pain, which was severe enough to cause the patient to come to the hospital. At that time he had signs of heart failure. The electrocardiogram showed changes from the previous record, but it must be remembered that he was probably taking digitalis, although it is not so stated in the record. I believe that this episode was also caused by myocardial infarction.

A fourth attack of severe pain, which occurred in the hospital, could have been due to a pulmonary or a myocardial infarct, most probably the latter. From this sequence of events I believe that there is no doubt that this man was suffering from severe coronary heart disease, with recurring episodes of myocardial infarction and possibly occasional pulmonary infarcts, and that he ultimately died abruptly in a manner characteristic of severe coronary disease.

Let us pass to the therapy, which introduces, I suspect, the real reason for bringing up this case — namely, the use of anticoagulants under these circumstances. During the past year there have been three reports in the literature concerning the use of anticoagulant therapy following acute myocardial infarction. The evidence is suggestive that such a procedure may be helpful in inhibiting complications. Statistics reported by Barker¹ indicate that following an acute myocardial infarct there is approximately a 35 per cent chance that patients within the first six weeks will have some form of thromboembolic complication, if one includes both peripheral thrombophlebitis and pulmonary infarcts, as well as thrombi in the heart and consequent peripheral emboli. Actually that figure seems too high to me. Nevertheless, the risk of such complications is considerable. In the face of this, anticoagulant therapy seems rational to prevent these thromboembolic complications. Furthermore, there has been at least one report mentioned by Barker¹

lized, midabdominal pains, but the bowels moved. A questionable mass was palpated in the lower quadrant. A month later the bowels were sluggish, and there was some distention but no pain. Seven months before admission an occasional, mild abdominal pain occurred. The abdomen was soft. A month before admission the bowel movements were loose, and there had been increasing anorexia and a weight loss of 10 to 15 pounds. Three weeks before admission barium-enema study was negative except for marked dilatation of the cecum and the ascending and the transverse colon. The distention became more persistent, and during the week before admission frequent enemas were required for relief, although the bowel movements were spontaneous and normal. The patient vomited small amounts once or twice daily. Four days before admission a colonic irrigation gave considerable temporary relief.

Some years before the present illness an appendectomy had been followed by a phlebitis in the right leg. There had been attacks of mild cystitis, one, two and one year before admission, each lasting from a week to a day. Ten years before admission the pelvis had been fractured in an automobile accident.

Physical examination disclosed an obese patient who nevertheless showed signs of weight loss. The abdomen was distended, soft and nontender. Peristalsis was increased. No mass was felt. There were external hemorrhoids. Rectal examination was negative.

The temperature was 98.2°F, the pulse 88, and the respirations 20. The blood pressure was 140 systolic, 80 diastolic.

Examination of the blood revealed a hemoglobin of 14.2 gm and a white-cell count of 9700, with 32 per cent neutrophils. The urine was normal. No ova, parasites or red cells were found in the stools on repeated examination. The stools were guaiac negative. A barium enema revealed an area of rather marked narrowing in the middle and upper sigmoid over a distance of approximately 12 cm. The lumen was irregular, and in the midportion there was an uneven area that could have represented a pocket extending beyond the bowel lumen. There were a few diverticula in the distal sigmoid, but none in the region of the narrowing. The margins of the latter were not shelved. Barium passed beyond the obstruction showed considerable fecal material in the dilated colon. The small bowel was also dilated. Fluoroscopically there was thought to be a shadow behind the heart, possibly a hernia, but this did not contain colon.

On the second hospital day, proctoscopic examination was negative up to 15 cm above the anus. The patient's condition continued unchanged for nine days, when a cecostomy and a prophylactic bilateral femoral-vein ligation were performed. The postoperative course was satisfactory. The

colon was drained by a Miller-Abbott tube inserted through the cecostomy. The small-bowel distention gradually decreased but did not disappear. The urinary output, which was low for two days, subsequently increased. The serum protein had dropped to 3.6 gm per 100 cc by the fifth postoperative day. The white-cell count reached a maximum of 16,000 on one occasion, a transfusion with 500 cc of blood was given at the time of operation, and again on the fifth postoperative day. On the twenty-third hospital day a second operation was performed.

DIFFERENTIAL DIAGNOSIS

DR FRANCIS D MOORE This woman in the seventh decade of life, after six years of vague abdominal rumbling, which presaged further trouble, developed abdominal symptoms in a gradual crescendo that reached a maximum at the time of admission, when the previous, rather vague and intermittent symptomatology yielded to symptoms of obstruction with anorexia and weight loss. The significant items of that six-year history are the duration and the finding, a year before admission, of diverticulosis with spasm in the sigmoid, justifying a diagnosis of diverticulitis. This bout of difficulty had evidently subsided spontaneously, only to recur on various occasions prior to admission, the most recent episode taking the form of an intensified version of the previous ones.

The past history does not cast a great deal of light on the present symptoms except that, since the appendix had been removed, we presumably need not worry about that as a source of the present trouble.

On physical examination, the patient was noted to be obese, which as I shall point out later is probably significant. Examination of the abdomen showed low-grade, large-bowel obstruction. The patient was not systemically ill and had little evidence on physical or laboratory examination of invasive infection. The negative guaiac test was of course of great interest and probably significant, although it would be nice to know whether multiple tests were carried out. The x-ray findings, needless to say, are of the greatest importance.

X-ray study revealed narrowing, with neighboring diverticulosis. We need not waste time on the well known fact that the diverticula involved in acute diverticulitis often do not show in the x-ray film, owing to the fact that they are filled with purulent material, to edema of the mucosa or to fecal material, or to a combination of the three. The significant facts are that the margins of the defect were not shelved and that some obstruction was produced. Dilatation of the small bowel simply indicates that the ileocecal valve was not competent. The negative proctoscopic examination is of little help one way or another, since the patient's lesion was well above 15 cm from the anus. The lack of

third day, he had a massive myocardial infarct. We have not yet had enough experience with this new project to make definite statements.

CLINICAL DIAGNOSIS

Coronary thrombosis, recurrent, with myocardial infarction

DR. BLAND'S DIAGNOSES

Coronary heart disease
Myocardial infarcts

ANATOMICAL DIAGNOSES

Coronary sclerosis, severe
Myocardial infarcts, anterior, old, and posterior, recent
Pulmonary congestion and edema
Horseshoe kidney

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: Post-mortem examination showed a considerably hypertrophied heart, which weighed 550 gm. All the branches of the left coronary artery were markedly sclerotic and partially calcified with fibrous narrowing. There were, however, minute pin-point lumens suggesting that thrombi had been recanalized. No acute change was found in the coronary arteries to explain why this man died at the particular moment that he did. The left ventricle showed two definitely separable areas of infarction. One on the anterior surface, well toward the apex, was very old and fibrous. The second one, which was found on the posterior surface and slightly toward the base, was also of considerable duration — some weeks at least. It was probably responsible for the third episode. The endocardium over both infarcts was thickened and sclerotic, but there were no fresh thrombi. The lungs showed marked congestion, indicating that there had been sudden left ventricular failure, which must have lasted for a few minutes before death.

The only other finding was an anatomical curiosity, a horseshoe kidney which I am sure had no significance.

On microscopic examination the liver showed a rather extensive fatty vacuolization — more than could be accounted for by heart failure — but could be explained by the alcohol to which the patient turned for consolation during the last few months of life. It had not progressed far enough, however, to produce any degree of liver insufficiency.

DR. CURRENS: One or two features of the clinical course were interesting. In a period of four months the patient had four episodes of pain entirely consistent with the diagnosis of coronary thrombosis. Because of these recurrent attacks, it was decided to place him on dicumarol therapy. He was certainly a suitable patient to follow for a time. All

four attacks of pain appeared at night, awaking him from a sound sleep. The blood pressure was found to be quite low, particularly in the morning, the diastolic pressure being 50 and the systolic 80 to 90. At the time of the pain, however, the arterial blood was able to constrict and produce moderate hypertension.

So far as dicumarol therapy is concerned, it was easy to carry him and maintain a prothrombin level between 20 and 40 per cent with 15 mg. of the drug after the initial dicumarolization. The dosage varies tremendously from patient to patient, and the individual daily dosage must be established if one decides to carry it over that length of time. The fact that there was no evidence of recent infarction or thrombosis may be significant.

DR. BLAND: It is also significant that the lungs were clear so far as pulmonary emboli were concerned.

Were the peripheral vessels examined?

DR. MALLORY: They were not examined, since we found no infarction in the lung.

Whenever a new drug is introduced the pathologist naturally looks for manifestations of toxicity. The only evidence of dicumarol toxicity described to date is extensive hemorrhage with uncontrolled dosage.¹ Patients have died with subarachnoid, gastrointestinal and renal hemorrhages. There was no manifestation in this case that could have been considered evidence of toxicity.

CASE 33062

PRESENTATION OF CASE

A sixty-seven-year-old housewife entered the hospital because of recurrent abdominal distention and pain.

Six years before admission the patient had had a single attack of abdominal pain, without diarrhea, for which no explanation was found. Five years later an attack of distention, with fever, constipation and abdominal distress, occurred. A plain film of the abdomen showed a large amount of gas and fecal matter distending the colon. The barium enema reached nearly to the splenic flexure. The whole descending colon was distended with feces and the patient was unable to retain the enema. There was considerable spasm in the sigmoid, and a few diverticula were seen. With colonic irrigation and mineral oil by mouth the symptoms ceased, only to recur again in ten days. Examination of the abdomen was negative except for distention, which cleared after a day or so. Eleven months before admission, the patient was having colicky, non-

lized, midabdominal pains, but the bowels moved. A questionable mass was palpated in the lower quadrant. A month later the bowels were sluggish, and there was some distention but no pain. Seven months before admission an occasional, mild abdominal pain occurred. The abdomen was soft. A month before admission the bowel movements were loose, and there had been increasing anorexia and a weight loss of 10 to 15 pounds. A few weeks before admission barium-enema study was negative except for marked dilatation of the cecum and the ascending and the transverse colon. The distention became more persistent, and during the week before admission frequent enemas were required for relief, although the bowel movements were spontaneous and normal. The patient vomited small amounts once or twice daily. Four days before admission a colonic irrigation gave considerable temporary relief.

Some years before the present illness an appendectomy had been followed by a phlebitis in the right leg. There had been attacks of mild cystitis, two and one year before admission, each lasting from a week to a day. Ten years before admission the pelvis had been fractured in an automobile accident.

Physical examination disclosed an obese patient who nevertheless showed signs of weight loss. The abdomen was distended, soft and nontender. Perianal skin was increased. No mass was felt. There were external hemorrhoids. Rectal examination was negative.

The temperature was 98.2°F, the pulse 88, and the respirations 20. The blood pressure was 140 systolic, 80 diastolic.

Examination of the blood revealed a hemoglobin of 14.2 gm and a white-cell count of 9700, with 32 per cent neutrophils. The urine was normal. No ova, parasites or red cells were found in the stools on repeated examination. The stools were guaiac negative. A barium enema revealed an area of rather marked narrowing in the middle and upper sigmoid over a distance of approximately 12 cm. The lumen was irregular, and in the mid-portion there was an uneven area that could have represented a pocket extending beyond the bowel lumen. There were a few diverticula in the distal sigmoid, but none in the region of the narrowing. The margins of the latter were not shelved. Barium passed beyond the obstruction showed considerable fecal material in the dilated colon. The small bowel was also dilated. Fluoroscopically there was thought to be a shadow behind the heart, possibly a hernia, but this did not contain colon.

On the second hospital day, proctoscopic examination was negative up to 15 cm above the anus. The patient's condition continued unchanged for nine days, when a cecostomy and a prophylactic bilateral femoral-vein ligation were performed. The postoperative course was satisfactory. The

colon was drained by a Miller-Abbott tube inserted through the cecostomy. The small-bowel distention gradually decreased but did not disappear. The urinary output, which was low for two days, subsequently increased. The serum protein had dropped to 3.6 gm per 100 cc by the fifth postoperative day. The white-cell count reached a maximum of 16,000 on one occasion, a transfusion with 500 cc of blood was given at the time of operation, and again on the fifth postoperative day. On the twenty-third hospital day a second operation was performed.

DIFFERENTIAL DIAGNOSIS

DR FRANCIS D MOORE This woman in the seventh decade of life, after six years of vague abdominal rumbling, which presaged further trouble, developed abdominal symptoms in a gradual crescendo that reached a maximum at the time of admission, when the previous, rather vague and intermittent symptomatology yielded to symptoms of obstruction with anorexia and weight loss. The significant items of that six-year history are the duration and the finding, a year before admission, of diverticulosis with spasm in the sigmoid, justifying a diagnosis of diverticulitis. This bout of difficulty had evidently subsided spontaneously, only to recur on various occasions prior to admission, the most recent episode taking the form of an intensified version of the previous ones.

The past history does not cast a great deal of light on the present symptoms except that, since the appendix had been removed, we presumably need not worry about that as a source of the present trouble.

On physical examination, the patient was noted to be obese, which as I shall point out later is probably significant. Examination of the abdomen showed low-grade, large-bowel obstruction. The patient was not systemically ill and had little evidence on physical or laboratory examination of invasive infection. The negative guaiac test was of course of great interest and probably significant, although it would be nice to know whether multiple tests were carried out. The x-ray findings, needless to say, are of the greatest importance.

X-ray study revealed narrowing, with neighboring diverticulosis. We need not waste time on the well known fact that the diverticula involved in acute diverticulitis often do not show in the x-ray film, owing to the fact that they are filled with purulent material, to edema of the mucosa or to fecal material, or to a combination of the three. The significant facts are that the margins of the defect were not shelved and that some obstruction was produced. Dilatation of the small bowel simply indicates that the ileocecal valve was not competent. The negative proctoscopic examination is of little help one way or another, since the patient's lesion was well above 15 cm from the anus. The lack of

blood on proctoscopy, however, corroborates the negative guaiac test

The initial operation performed — namely, a cecostomy and prophylactic bilateral femoral-vein ligation — is of some interest from a technical point of view, because it might have been predicted that a transverse colostomy would be a more satisfactory initial procedure in this particular patient. I imagine that prophylactic bilateral femoral-vein ligation was carried out not only because of the patient's age and the disease but also because of the previous phlebitis. After this operation the colon was drained by a Miller-Abbott tube inserted through the cecostomy, an ingenious method of large-bowel lavage worked out by Dr. J. B. Millet.¹ Again, I should like to know what disease the surgeons thought they were dealing with because, even with Miller-Abbott lavage of the large bowel through a cecostomy, I should not consider the bowel adequately prepared for resection of an inflammatory process. After this operation the urinary output was low for two days but subsequently increased, suggesting that the physiologic disturbance incident to operation was greater than had been expected. At the end of that time the serum protein was 3.6 gm. per 100 cc., and one wonders if this was an accurate determination or if the patient had possibly been overhydrated in an attempt to restore the renal function. On the twenty-third hospital day, after a transfusion, a second and presumably definitive operation was performed.

The differential diagnosis lies between carcinoma of the sigmoid and diverticulitis. There are a few other extremely rare conditions to be considered, such as endometriosis, invasion of the large bowel by tumor of a neighboring viscus and some of the rarer bowel tumors.

Because of the fact that the patient had had symptoms for six years, as well as a known diverticulosis and typical diverticulitis with spasm a year previously, and because of the negative guaiac test and the fact that no shelf was visible in the x-ray film, I take the point of view that the patient had diverticulitis, with spasm and obstruction, and a small area of localized perforation represented by the pocket of barium outside the lumen. She obviously had little systemic reaction to this perforation, which was probably chronic and caused no elevation of the white-cell count or temperature.

From time to time someone gets up enough curiosity concerning the subject of diverticulitis to look up a series of cases of this disease. Reviews by Smithwick,² in 1942, and Morton,³ in 1946, are examples of such clinical investigation. It might be worth while to review some of the figures in one of those articles and to determine whether our analysis of this case agrees with the figures in the article. According to Morton, diverticulosis is found in approximately 7 per cent of all post-mortem

examinations. This is merely another way of saying that one should not be too much influenced by the diverticula found in the x-ray picture.

In 200 cases of diverticulitis, 111 patients entered the hospital with diverticulitis and spasm, meaning that local narrowing in the sigmoid was an accompaniment of the systemic manifestations. The combination was noted in obese patients about four times as often as it was in thin patients and was equally distributed between men and women. Essentially all the patients were over forty years of age, and 94 per cent had pain as the outstanding symptom. About a third of these patients had distention, and it is of interest that in Morton's series 24 per cent gave a distinct history of having passed bloody stools and that in 32 per cent the benzidine test was positive for occult blood. This evidence shows that blood in the stools does not rule out diverticulitis, it is obviously important to mention, however, that with blood in the stools one must be suspicious of the diagnosis of diverticulitis and treat such patients with the presumption that carcinoma is present. In this particular case, however, since the guaiac test was negative and proctoscopic examination revealed no blood, the diagnosis inclines toward diverticulitis.

In Morton's series, 85 patients, or slightly less than 50 per cent, had various complications of diverticulitis. These complications were equally divided between perforation and obstruction, it is worthy of note, however, that perforation carried a 30 per cent mortality. It is also of the greatest importance to observe that 17 of these patients had carcinoma. The neoplasms were in the sigmoid in 12 cases and elsewhere in the colon in 5. This may be stated otherwise by pointing out that 10 per cent of patients who have diverticulitis with complications also have carcinoma of the colon. The significance of this consideration in evaluating this particular patient is obvious.

It is also worthy of note that 25 per cent of the obstructed patients also had a small abscess, which would apply to this patient, and that 50 per cent of the obstructed cases were completely obstructed. The patient in the case under discussion was not completely obstructed.

Thus, when we try to determine how this patient fits into the broad picture of diverticulitis, we see that in many ways she is quite typical of patients with the disease.

That brings us to the final point of the difference between the surgical diagnosis and the surgical strategy in handling a case. My diagnosis in this case is diverticulitis, with partial large-bowel obstruction and a small localized perforation producing an abscess.

In dealing with this patient, however, one must consider the lesion to be carcinoma until it is proved otherwise. By this I mean that, even when the

ologist has the specimen on the table, he may be able to tell whether or not a cancer is present, the operation carried out must be radical enough to satisfy the requirements of cancer surgery. In view of the fact that considerable inflammatory mass may be present, the bowel should be prepared in such a way that a safe resection can be made, if the lesion is diverticulitis — that is, by a transverse colostomy that comes as close to defunctioning the colon as is possible. It is my feeling in this particular case another, possibly less satisfactory, maneuver was carried out, although it is only fair to say that on admission the patient may have had such a dilated colon that a satisfactory transverse colostomy would have been difficult and dangerous of accomplishment. In any event, after a suitable period of defunctioning of the distal colon with an attempt to produce a surgically satisfactory and bacteriologically clean if not sterile bowel, an adequate radical resection of the area could be carried out with a diagnosis of diverticulitis or with a strong suspicion of carcinoma.

CLINICAL DIAGNOSES

Diverticulitis
Carcinoma of sigmoid

DR MOORE'S DIAGNOSIS

Diverticulitis, possibly with superimposed carcinoma

ANATOMICAL DIAGNOSIS

Diverticulitis, acute and chronic

PATHOLOGICAL DISCUSSION

DR TRACY B. MALLORY: The specimen received at the laboratory was a segment of sigmoid measuring 25 cm in length. The middle third was markedly thickened and narrowed and felt quite firm. Its serosa was covered with fibrin, the bowel wall was thickened to 6 mm, and the mucosa was thrown into pseudopolypoid folds. Numerous diverticula were present in both the constricted portion and the proximal sigmoid above it. As Dr Moore prophesied, it would have been impossible to exclude carcinoma on gross examination, but many microscopic sections showed only acute and chronic inflammation.

DR ARTHUR W. ALLEN: Dr Moore has summed up this situation admirably. There was no question about the diagnosis of diverticulitis in this case. We were, however, confronted with problems that were perhaps not made entirely clear in the record. One was that, in spite of all our efforts, this woman maintained a serum protein level of about half the normal. We believed that she was much too distended at the time she came in for a transverse

colostomy, which would have been the operation of choice. Also, she had dilated loops of small bowel, which might have indicated an incompetent ileocecal valve but were later proved to have been due to partial obstruction of the small intestine caused by adhesions to the inflammatory mass.

A cecostomy was done as a temporary measure. We had expected to do a transverse colostomy later after the decompression had partly subsided. Millet's method of deflating the colon with the Miller-Abbott tube was quite effective, but the patient still seemed to have dilated loops of small intestine. This caused us to attack the problem of relieving her of the secondary small-bowel obstruction. When the area was exposed, it was evident that she could not have improved had not the loop of small bowel attached to the inflammatory lesion been freed. This was easily accomplished, and it was not necessary to resect any small bowel. Instead of stopping at this point and hoping that the areas of small intestine would not become reobstructed, we elected to remove the disease in the sigmoid at the same time. A number of factors were involved in this decision.

We were dealing with a patient who, first of all, refused to have any surgery done. After five days, she agreed to let us proceed. When we told her that she would need three operative procedures before she was well, — namely, transverse colostomy, removal of the lesion at some later date and, finally, closure of the transverse colostomy, — she simply refused. A cecostomy was done, in the hope that possibly we might avoid a three-stage procedure and make it a two-stage operation.

At the second operation, after the small bowel had been freed, the sigmoid was carefully examined and felt not like diverticulitis alone but definitely like carcinoma. This influenced us somewhat in proceeding with a resection of the sigmoid at that time. We have seen carcinoma and diverticulitis associated in several cases and were swayed by this in removing this segment of the sigmoid. It proved, however, that diverticulitis with a phlegmonous mesentery of the bowel was the true situation and that no cancer was present.

DR MOORE: Dr Allen's comments have filled out the picture in a fashion that would be difficult to put in the case protocol. Excessive distention certainly made an initial transverse colostomy impossible, and the continuing small-bowel obstruction forced the issue before further colonic preparation could be carried out.

My comments about the methods of preparation of the bowel were intended merely to bring out the point that adequate preparation of the segment to be resected is of the greatest importance if one is dealing with diverticulitis alone. One or two near disasters that we have had on the surgical service in the last two years, which resulted from resection

with inadequately prepared bowel, merely point out the significance of these considerations in diverticulitis.

The real difficulty, however, from a practical point of view, is nicely demonstrated by this patient and therefore is possibly worth an additional word. The problem can be stated as follows: if one is dealing with carcinoma, a resection after a week or two of preparation even by cecostomy alone, with or without the Millet device, is perfectly satisfactory, and in dealing with diverticulitis a total defunctioning transverse colostomy, with a rest of several months, is ideal. Yet from Morton's figures and those of others we find that diverticulitis and carcinoma coexist so frequently that the surgeon is often taking on himself an inordinate risk by letting the patient with what is considered to be diverticulitis rest at home for four to six months before resection is done.

Because of this fundamental problem and the difficulty of ruling carcinoma in or out we are often forced to a sort of compromise that in the occasional

case of diverticulitis alone produces " " results. I recall well a patient in whom this differential choice existed and in whom I carried out a combined abdominoperineal resection with extensive pelvic dissection and, of course, a perineal colostomy, only to find that there was nothing but diverticulitis in the specimen.

I think that we should therefore give all the encouragement we can to those who are working on more adequate methods of diagnosing the presence of carcinoma.

DR MALLORY: The postoperative complications that were feared developed in this patient. Gangrene of the bowel occurred on either side of the suture lines, followed by perforation and general peritonitis. There was a terminal bronchopneumonia.

OLIC ACID

THE term "folic acid," originally used for a substance in spinach required for the growth of *Streptococcus lactis* R, is now applied to a group of substances found in yeast, liver, green leaves, cereals and other foods that are considered to be members of the vitamin B complex. The group includes vitamin B₁₂, required for the prevention of nutritional anemia in chicks, vitamin M, necessary for the prevention of nutritional cytopenia and a sprue-like syndrome in monkeys, and factors needed to prevent nutritional anemia in rats treated with sulfonamides to inhibit vitamin synthesis by intestinal bacteria. Also included are factors promoting the growth of *Lactobacillus casei* and *Str. lactis* R. The *L. casei* factor, also effective in the treatment of the animal nutritional deficiency syndromes men-

tioned above, has been isolated from liver and synthesized. It is a compound of a pteridine, related to the yellow color in butterfly wings, para-amino benzoic acid, a well known antagonist of sulfonamides, and glutamic acid, an amino acid, and has been named pteroylglutamic acid. Conjugates of this substance with two or six additional glutamic acid groups have also been isolated.

The interest to the medical profession in this group of substances lies in the ability of some of them to produce remissions in several nutritional macrocytic anemias, including pernicious anemia, and especially in the relation between pteroylglutamic acid and its conjugates and the principle in liver effective in Addisonian pernicious anemia.

The amount of solids in purified liver extracts is far less than the amount of folic acid required to give comparable hematologic effects, and the folic acid content of such liver extracts is negligible. In contrast to liver extract, folic acid is equally effective orally and by injection. It is thus clear that folic acid is not the principle in liver extract effective in pernicious anemia, nor is it the extrinsic (food) factor or the intrinsic (gastric) factor described by Castle. Folic acid does not restore the secretory activity of the stomach in pernicious anemia, at least so far as hydrochloric acid is concerned.

Liver principle is thought to produce folic acid, possibly by aiding enzymes known as conjugates in releasing free folic acid from the conjugated forms in which it appears in foods.¹ Folic acid, in turn, may act as an enzyme in the production of 5-methyluracil (thymine), a component of nucleic acid, which is also effective in pernicious anemia and related states but only in doses over a thousand times as great as that of folic acid.²

Nutritional macrocytic anemias that respond to injections of purified liver extract are thought to arise because of deficient intake of extrinsic factor, defective secretion of intrinsic factor or defective absorption of these substances or products of their interaction. Combinations of these mechanisms frequently exist. As was first shown by Spies and his associates,³ folic acid acts approximately as well on the blood and bone marrow in these cases as purified liver extract. This group of anemias includes Addisonian pernicious anemia, megaloblastic anemia of

infancy and some cases of nutritional macrocytic anemia occurring with poor diets alone or in association with sprue, pellagra, chronic alcoholism, carcinoma of the stomach or pregnancy. In sprue it has been claimed that the stools improve and that the intestinal motility, atrophied mucous membranes and glucose-tolerance tests return to normal.

Purified liver extracts in the usual doses effective in Addisonian pernicious anemia do not relieve the anemia due to a deficiency of Wills's factor.⁴ The anemia can, however, be corrected promptly by crude liver preparations. Such cases have been noted in association with defective diets, either alone or accompanying pregnancy or steatorrhea. Only three such cases have been treated with folic acid.⁵ The response was partial, and further improvement followed crude-liver therapy.

The effective dose of folic acid is 5 to 20 mg daily by mouth or by injection, 10 mg daily being sufficient in most cases to produce remissions comparable to those obtained with purified liver extracts. Daily dosage seems advisable, since patients treated in this way may show maintenance of normal blood counts, whereas results are less satisfactory if folic acid is given in large doses every one or two weeks. This is not surprising in view of the fact that one third to one half of a 10-mg dose of folic acid may be lost in the urine within twenty-four hours. No toxic effects have been noted with single doses as large as 400 mg.

Folic acid as a practical therapeutic agent does not, however, directly provide "new hope for anemics." Thus, there is no anemia that folic acid relieves that is not also relieved by liver extract. Crude liver extracts have produced complete remissions in cases due to a deficiency of Wills's factor after failure of folic acid to do so. Liver extracts are effective in the prevention and arrest of combined system disease, whereas there is growing evidence that neurologic disturbances in pernicious anemia may remain unaltered or even progress, sometimes in a rapid and dramatic fashion, under folic acid therapy, even when the red-cell count is maintained at a normal level.⁶

Two features of folic acid have been claimed as therapeutically useful. In the first place, it is suggested that oral therapy would remove the necessity

for repeated injections. This, however, appears to be a disadvantage in pernicious anemia, since neglect of therapy occurs too frequently when patients treat themselves with oral medicines. In any case the possibility of neurologic complications outweighs any advantage that the oral route of treatment may have. Good health is usually maintained in pernicious anemia with an injection of 1 or 2 cc of purified liver extract as seldom as every two or four weeks. Secondly, folic acid has been recommended for cases allergic to liver extracts. Dr. C. S. Davidson,⁷ however, has recently shown that in a series of fourteen cases sensitive to pork-liver extract given parenterally all cases reacted favorably to beef-liver extract in spite of skin tests in some cases showing apparent sensitivity to the latter. These findings, together with the arguments mentioned above, make the use of folic acid in these cases unnecessary and undesirable.

Like liver extract, folic acid has failed to produce remissions in refractory and aplastic anemias, leukemias, myelophthisic anemias and megaloblastic deficiency anemias, as well as in neutropenias occurring spontaneously or those due to sulfonamides, thiouracil or influenza. The possible beneficial effect of folic acid on the neutropenias due to exposure to radium and x-rays should be readily subject to analysis by animal experiment.

TIME OUT

EVEN physicians need vacations whether they know it or not. One grows older insensibly, our confreres recognize this aging in us while we ourselves frequently do not. So likewise our professional duties pall, be it ever so gradually, our patients' little aches and pains, so real to them, irritate and we are prone to brush them aside as irrelevant.

important. We lose interest in our work and, perhaps, become irritable to others, and that very irritability galls us and makes us still more irritable. Headaches and pains of no great moment. Our doctor tells us that they are due to this or organic defect — which, incidentally, we have for the past ten years. This train of events increases in geometric proportion until something happens, and even we ourselves recognize that we must leave the traces and be off, come hell or high water.

There are some physicians who, in actuality, do need a vacation in the true sense of the word. The fortunate persons can keep themselves in fine fettle both mentally and physically by taking a long weekend in the country now and then as the spirit moves them. They are to be envied. There are others who “knit up the unravelled sleeve of care” by throwing themselves into the noisome turmoil of a large city. The great Nissl is said to have taken his time off by packing a small suitcase half of cigars, covering them with a piece of cardboard and filling the remaining space with cigars. He traveled by train — to nowhere in particular — until the intervening cardboard was reached. Then retraced his steps. In other words, there are all sorts of vacations.

Where does the physician's physician fit into this picture? As a rule his problems are three. Is there something really wrong? What is it? What should be done about it? Not infrequently the first question is the most difficult of all. There is both conscious and unconscious malingering. There is both conscious and unconscious rationalization of one's signs and symptoms. There is the unconscious tendency of the physician-patient to put two and two together and make five, just as there is, at times, a cheerful effort to put five and five together and garner one. The physician is notoriously a difficult patient. At knowledge he has, be it great or small, is liable to become distorted. He usually cannot evaluate his symptoms in an objective and dispassionate manner. Indeed, it is the rare physician who can sit back and simply and without emotion “Behold, I have a symptom. What shall I do about it?”

If this editorial seems to wander from the subject, it is because physicians, unless confronted by a concrete problem, are prone to do just that. The thesis

is simply this: some men are ill and need meticulous care and protection, whereas others with symptoms no less severe are simply worn out mentally and physically and in grievous need of a vacation. It is then the attending physician's problem to size the situation up — to be sure that there is nothing really wrong — to take such measures as are necessary to prove that this is the case and then to insist that his patient take a vacation, one to his own liking and, above all, *enrêlé*. To place a sharp limit on the duration of a tired man's vacation automatically nullifies its beneficial effect.

It takes a brave and sagacious man to say to a fellow physician with marked symptoms “Do you really want to take that trip? Then do.”

MISCELLANY

NOTES

The appointment of three new professors at the Harvard Medical School has been recently announced. Dr Robert E. Gross has been made William E. Ladd Professor of Child Surgery and head of the Department of Surgery at the Children's Hospital. Dr William T. Green becomes clinical professor of orthopedic surgery and director of orthopedic surgery at the Children's Hospital. Dr Joseph S. Barr becomes clinical professor of orthopedic surgery and director of orthopedic surgery at the Massachusetts General Hospital.

The following Massachusetts physicians were recently appointed fellows in the American College of Surgeons: Ronald W. Adams, Boston; Felicia A. Banas, Boston; James B. Blodgett, Boston; Francis M. Burke, Nauck; Bradford Cannon, Boston; George D. Dalton, Quincy; Lawrence R. Dame, Greenfield; John F. Flynn, Pittsfield; George R. Gagliardi, Framingham; Ilija Galleani, Boston; Francis M. Ingersoll, Boston; Aurel G. Lavoie, Springfield; Samuel Levine, Lynn; Saul M. Marcus, Boston; Carroll C. Miller, Boston; Daniel L. Moonen, Fall River; Francis D. Moore, Brookline; Daniel J. Mullane, Brookline; Philip E. Mullane, Lowell; John A. Reidy, Boston; Arnold L. Segel, Boston; Clarke Staples, Malden; Joseph M. Stowell, Boston; and Charles L. Sullivan, Brookline.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Radio in Health Education. Prepared under the auspices of the New York Academy of Medicine. 8°, cloth 120 pp. New York: Columbia University Press, 1935. \$1.60.

This monograph is the first in a new series, entitled *Frontiers in Public Health Education*, and is intended for the use of health educators, social workers, radio personnel, health organizations and all others concerned with public health. The first part of the text is a critical analysis of radio broadcasting made under the auspices of the New York Academy of Medicine. The second part consists of papers presented at a public-health conference held in December, 1943, at which the various aspects of the radio program were discussed. An appendix gives a response analysis of a series of talks, entitled “Highways to Health,” given over the air during the period from June 9, 1935, to November, 1939. A total of two hundred and twelve auditions were given on twenty-six different subjects. The number of talks on each

subject varied from thirty-nine on the problems in the care of children to two on varicose veins, goiter and other subjects. The average response was one hundred and ninety-four, and two tables show the responses higher and lower than the average. The highest response (nine hundred and twenty) was to a talk on the skin troubles of the young, and the lowest (two) was on the care of the skin in summer. It is interesting that the second highest response (nine hundred) was on arthritis. The radio is an instrumentality of communication with enormous potentialities, and the material presented in this monograph comprises a basic and critical evaluation of objectives and technics in radio health education. This monograph should be in all medical libraries and should prove valuable to all persons interested in public health.

The Diagnosis of Nervous Diseases. By Sir James Purves-Stewart, KCMG, CB, Knight of St John of Jerusalem, M.D. (Edin.), FRCP, consulting physician to Westminster Hospital, West End Hospital for Nervous Diseases and Royal National Orthopaedic Hospital. Ninth edition. 8°, cloth, 880 pp., with 358 illustrations. Baltimore: The Williams and Wilkins Company, 1945. \$11.00.

This standard work, whose first edition was published in 1906, has been consistently revised throughout all its editions. The work has been rewritten so far as possible amid the strains of World War II. The author, while traveling from the United States to England in 1943, lost all his manuscripts and notes by enemy action and therefore had practically to rewrite the whole book on the basis of previous editions and material available in London.

Pediatric X-Ray Diagnosis: A textbook for students and practitioners of pediatrics, surgery and radiology. By John Caffey, M.D., associate professor of pediatrics, College of Physicians and Surgeons, Columbia University, associate pediatrician and roentgenologist, Babies Hospital and Vanderbilt Clinic, New York City, and consulting pediatrician, Grasslands Hospital, Westchester County, New York, and St John's Hospital, Yonkers, New York. 4°, cloth, 838 pp., with 710 illustrations. Chicago: The Year Book Publishers, Incorporated, 1945. \$12.50.

This is the first complete book on roentgenologic diagnosis in pediatrics published in English since that of Thomas Morgan Rotch, of Boston, on the diagnosis of diseases in early life by the roentgen method, issued in 1910. The author has based his work on the roentgenologic conferences held semimonthly at the Babies Hospital, New York City, during the last twenty years. The purpose of the work is to describe the shadows cast by normal and morbid tissues and the clinical appraisal of roentgenologic findings in pediatric diagnosis. Physics, technic and therapy have been omitted intentionally. To each topic is appended a short list of references to the literature. The book is well printed, with a good type, on coated paper. The illustrations are clear, and the roentgenograms clearly defined. This book should prove valuable in all medical-reference collections.

Surgical Treatment of the Motor-Skeletal System. Supervising editor Frederic W. Bancroft, M.D., associate clinical professor of surgery, Columbia University, attending surgeon, New York City and Beth David hospitals, consulting surgeon, Veterans Administration, Lincoln and Harlem hospitals, New York, and Kings Park State Hospital, Kings Park, New York. Associate editor Clay R. Murray, M.D., professor of orthopedic surgery, College of Physicians and Surgeons, Columbia University, attending surgeon and chief of the Fracture Service, Presbyterian Hospital and Vanderbilt Clinic, New York City, consulting surgeon, Hackensack General Hospital, Hackensack, New Jersey, Sharon Hospital, Sharon, Connecticut, and St. Joseph's Hospital, Far Rockaway, New York. Part One: *Deformities, Paralytic Disorders, Muscles, Tendons, Bursae, New Growths, Bones, Joints, Amputations*. 4°, cloth, 641 pp., with 520 illustrations and a color plate. Part Two: *Fractures, Dislocations, Sprains, Muscle and Tendon Injuries, Birth Injuries, Military Surgery*. 4°, cloth, 639 pp., with 543 illustrations. Philadelphia: J. B. Lippincott Company, 1945. \$20.00.

This new treatise, a composite work of forty-three authorities in their particular fields, is primarily on surgical treatment, and therefore no attempt has been made to present the diagnostic problems or the etiology of the conditions in general. Selected lists of references are appended to each chapter. The text is well printed, with a good type, on paper, but because of the necessity of using coated paper for the illustrations, the volumes are rather heavy for their size.

A Handbook on Diseases of Children including diseases of the common fevers. By Bruce Williamson, M.D. (Edin.), FRCP (Lond.), physician, Royal Northern and Prince of Wales hospitals, London, and physician (E.M.S.), Wellbarn Hospital, Barnet. Fourth edition. 12°, cloth, 388 pp., with 81 illustrations. Baltimore: The Williams and Wilkins Company, 1945. \$4.50.

This fourth edition of a popular manual designed for medical students has been thoroughly revised, and recent advances in pediatrics have been introduced throughout the text. The colored plates, first introduced in the third edition, have been retained in this edition.

The Science and Art of Medicine: An inaugural lecture. By Sir Lionel Whitby, CVO, MC, MD (Cantab.), FRCP (Lond.), DPH, Regius Professor of Physics, University of Cambridge. 12°, paper, 24 pp. New York: Cambridge University Press, The Macmillan Company, 1946. 50 cents.

In this inaugural address on assuming the office of Regius Professor of Physics, Cambridge University, Dr. Whitby briefly outlines the work of his predecessors, and selects for a brief exposition one aspect of scientific medicine, that of chemotherapy.

Pharmacology. By J. H. Gaddum, Sc.D., MRCS, LRCP, professor of pharmacology, University of Edinburgh. Oxford: Medical Publications. Second edition. 8°, cloth, 460 pp., with 75 illustrations and 17 tables. New York: Oxford University Press, 1945. \$6.00.

This second edition of a textbook written primarily for medical students has been brought up to date and improved in other ways. A limited number of references have been incorporated throughout the text. An appendix on the interpretation of chemical names should be found helpful. The material is well organized and well printed on a good paper with a large type and the manual should prove valuable as a short text on its subject.

NOTICES

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, FEBRUARY 13

FRIDAY, FEBRUARY 14

*9:00-10:00 a.m. Clinicopathological Conference. Drs. Chester S. Keefer and H. E. MacMahon. Joseph H. Pratt Diagnostic Hospital.

*10:00 a.m.-12:00 p.m. Medical Staff Rounds. Peter Bent Brigham Hospital.

12:00 p.m.-1:00 p.m. Clinicopathological Conference (Boston Floating Hospital). Joseph H. Pratt Diagnostic Hospital.

MONDAY, FEBRUARY 17

*12:15-1:15 p.m. Clinicopathological Conference. Peter Bent Brigham Hospital.

TUESDAY, FEBRUARY 18

12:00 p.m.-1:00 p.m. Dermatological Service. Grand Rounds. Amphitheater. Dowling Building, Boston City Hospital.

*12:15-1:15 p.m. Clinicoradiological Conference. Peter Bent Brigham Hospital.

WEDNESDAY, FEBRUARY 19

*9:00-10:00 a.m. Pediatric Clinicopathological Conference. Drs. James M. Barry and H. E. MacMahon. Joseph H. Pratt Diagnostic Hospital.

*11:00 a.m.-12:00 p.m. Medical Clinic. Amphitheater. Children's Hospital.

REHABILITATION OF PATIENTS TOTALLY PARALYZED BELOW THE WAIST, WITH SPECIAL REFERENCE TO MAKING THEM AMBULATORY AND CAPABLE OF EARNING THEIR LIVING*

III. Tidal Drainage, Cystometry and Bladder Training

DONALD MUNRO, M D †

BOSTON

TIDAL drainage, cystometry and bladder training are interdependent. When properly used in combination they ensure that every patient who has had an injury to the spinal cord, conus or cauda equina and who is intelligent and co-operative will have infallible twenty-four-hour control of urination regardless of the severity of the cord injury. This paper is devoted to a description of the necessary apparatus and a discussion of the technic of these three therapeutic aids in such cases.

TIDAL DRAINAGE

Tidal drainage is a method whereby the urinary bladder can be alternately and automatically filled and emptied, the intravesical pressure constantly maintained at a predetermined level, puddling of residual urine and overstretching or shrinkage of the bladder wall prevented and the bladder maintained in a close approximation to a physiologically normal state even when completely separated from the suprasegmental part of the central nervous system. Although the apparatus, which was first described in 1935,¹ has subsequently been modified and improved, the principle of operation remains the same. Its proper use depends primarily on cystometrographic demonstration of the type of bladder that is to be served. Those hydrodynamic laws that have to do with siphonage determine its activity. Its proper functioning depends on the maintenance of an airtight siphon system during the period of emptying of the bladder.

Siphonage is activated whenever a predetermined intravesical pressure has been reached. The siphon is broken and inactivated by the admission of air as soon as the bladder is emptied. The apparatus is thereby left in such a condition that the cycle can start over again. The control of the admission of air into the system was accomplished in the

original apparatus by the use of a water trap. This trap had to be filled before the bladder was filled and before the siphon system could be made airtight, it had to be emptied after the bladder had been emptied before the siphon could be broken. Subsequent improvements led the irrigating fluid directly to the bladder² rather than by way of the trap (Fig. 1) and then replaced the trap with a capillary tube.³ The bore of this tube is too small to permit enough air to enter to break the siphon so long as the system contains any fluid. Through the ingenious use of a four-outlet Carrel-Dakin glass connector, a built-in cystometer is included along with this air vent (Fig. 2). Finally, the air vent and cystometer have been amalgamated⁴ by the use of a tube with a large enough bore to act as a cystometer, the apparatus is given the features of the air vent by being made airtight except for the air that enters and escapes through a hypodermic needle thrust through a rubber connection at its top (Fig. 3). All previous models have been abandoned in favor of these last two, which have been given extensive and thorough trials in my clinic. Both are entirely and equally satisfactory if properly constructed, set up and used. Neither is adequate unless used in conjunction with cystometrograms made once a week, or oftener if the occasion requires it.

Construction of the Tidal-Drainage Apparatus

As will be seen from Figures 2 and 3, there are certain parts of the apparatus that are common to both models. These are the following:

A wooden stand, equipped for attachment to the foot or head of the bed, measuring $6\frac{1}{2}$ feet long by 4 inches wide and with a shelf 6 by 6 by 1 inches at either end and on opposite sides. A centimeter scale marked every 0.5 cm. with its zero at the same level as the patient's pubis, is applied to the side of the upright that the lower shelf is on, the zero indicating the bladder level referred to in the figures and the text below.

A 2500-cc. aspirator bottle to which an airtight Murphy dropper that does not have a hole in its side is attached by

*From the Department of Neurosurgery, Boston City Hospital.
†Assistant professor of neurosurgery, Harvard Medical School; associate professor of neurosurgery, Boston University School of Medicine; chief, Department of Neurosurgery, Boston City Hospital.

an appropriate length of rubber tubing, an adjustable compression clamp controlling the rate of flow through the dropper. The aspirator bottle is strapped in place on the top shelf of the stand and the inlet is closed with a sterile gauze or cotton plug.

A waste bottle corked with a doubly perforated stopper containing short pieces of glass tubing in the perforations.

A No 16 Fr soft-rubber rectal tube for use as a catheter in male patients, and either that or a No 16 Fr soft-rubber

connector is 5 cm below the bladder level and so that the cystometer tube lies beside the centimeter scale that is on the wooden upright.

A Y tube. The aspirator bottle and attached airtight Murphy dropper are connected by a sufficiently long piece of rubber tubing to one arm of the Y tube, whose upright is inserted in the open end of the catheter. Another equally long piece of rubber tubing is led from the other arm of the Y to the open end of the Carrel-Dakin connector.

A length of small (inside diameter, 3 to 5 mm) rubber tubing, attached to the third side opening of the Carrel-Dakin connector. This tubing is carried upward to some point higher than the bladder level, passed through a loop of siphon (this makes the siphon curve) and then led downwards, attached to one of the glass tubes in the cork in the waste bottle. The other glass tube remains open. The waste bottle stands on the lower shelf of the wooden upright.

To construct the apparatus shown in Figure 1, the following material is needed in addition to the basic equipment listed above:

A piece of glass tubing 70 cm long and with a bore of about 3 mm (the cystometer tube), whose upper end is at

FIGURE 1 Original Tidal-Drainage Apparatus as Modified by MacNeill and Bowler²

mushroom catheter for use in female patients, held in place by appropriate adhesive strapping applied to the penis or the pubis respectively. It is important that the maximum size of the catheters be limited to No 16³.

The irrigating fluid used in both models is either Solution M or Solution G⁶. It is sterilized by autoclaving in the usual manner.

To construct the apparatus shown in Figure 2, the following additional material is needed:

A four-outlet (three lateral and one terminal) Carrel-Dakin glass connector.

A glass capillary tube 70 cm long. This is the air vent and is attached by rubber tubing to the center of the three side openings of the Carrel-Dakin glass connector.

A piece of glass tubing 70 cm long with an inside bore of about 3 mm. This is the cystometer tube and is attached to the lateral opening that is closest to the closed end of the Carrel-Dakin glass connector by a piece of rubber tubing surrounded by a compression clamp, which is closed when the apparatus is used for tidal drainage and opened when it is used as a cystometer. The Carrel-Dakin connector, with the air vent and cystometer tube attached, is strapped to the wooden upright in such a position that the horizontal center line of the

FIGURE 2 Tidal-Drainage Apparatus as Devised by Stewart. The trap is replaced by a capillary tube, and there is a built-in cystometer.

attached by a short piece of rubber tubing to the outlet of the airtight Murphy dropper.

A hypodermic needle with a patent bore, which is thrust through one wall of the rubber tube. This is the air vent.

A Y tube, one of whose arms is joined by rubber tubing to the lower end of the cystometer tube, the upright being connected to the open end of the catheter with the help of rubber tubing and glass connectors. The cystometer is

he attached Y tube are then strapped to the wooden in such a way as to place the former beside the center scale with its lower end 5 cm below the bladder

length of small rubber tubing (inside diameter 3 to 5 mm), which is led upward from the other arm of the Y tube to a point higher than the bladder level, passed through a piece of adhesive (this makes the siphon curve) and then led downward to be attached to one of the glass tubes in the cork of the waste bottle, the other glass tube remaining open. The waste bottle is placed on the lower shelf of the wooden stand

In this apparatus the 70-cm glass tubing serves not only as part of the irrigating system but also as the graduated arm of a cystometer and, by virtue of the hypodermic needle, as an air vent

The catheter should be removed, cleaned, re-sterilized and replaced — if again needed — once a week. Both types of apparatus should be taken down, cleaned and re-sterilized once a week while in use

It has been the custom in my clinic to attach the apparatus to the foot of the bed, but they work equally well when attached to the head or when mounted on an operating upright

Causes of Functional Failure

No matter which model is used certain simple precautions must be observed in its operation otherwise the apparatus will fail to work. This usually happens because the siphon is broken prematurely. As a result, the bladder either is not permitted to fill sufficiently to raise the intravesical pressure level to the desired height or is not completely emptied at each cycle

Air leaks, which are the most frequent cause of trouble, generally develop because of either or both of two mistakes. The usual one is to attempt to use a Murphy dropper with a hole in its side instead of the recommended type. Such a hole is excessive when used with either model and especially so with the combined cystometer-tube air vent (Fig 3), where it is too large to act as a substitute for the hypodermic needle. As a result, too much air enters the system. Even if it is closed with a piece of adhesive tape or bone wax, or both, and whether or not a hypodermic needle is stuck through the adhesive plaster, air leaks through because the suction effect during emptying is strong enough to pull air through the tape and to loosen the wax. The other mistake is to use rubber tubing that has too large an inside diameter for the siphon itself. This applies to both models. During emptying in such a case, the column of liquid flows only down the wall of the tube. Air is thus permitted to rush in through the unsealed center. A tube that is small enough to make the fluid column solid prevents this. In the model illustrated in Figure 2, an air leak may also develop if the clamp at the base of the cystometer tube is not tightly shut

Another cause of trouble is the formation of a trap in the long catheter connections. This occurs when the tubes are permitted to hang in a loop below the

level of the mattress. These rubber tubes should be pinned to the bedclothes on top of the mattress

Kinks in the connections, clamps that have been put on to stop the flow temporarily and then have not been removed, improperly placed catheters and hypodermic needles occluded by rust are further sources of trouble

Leakage of urine around the catheter occurs only because the apparatus has not been properly ad-

FIGURE 3 Stewart's Modification of the Tidal-Drainage Apparatus as Modified by Cone and Bridgers⁴
A hypodermic needle is substituted for the capillary tube

justed to the type of bladder it is serving. The remedy is to readjust the tidal-drainage apparatus after a cystometrogram has provided the necessary information regarding the stage of bladder recovery. The one thing not to do for this difficulty is to increase the size of the catheter — this will not stop the leak and will cause urethritis, epididymitis, prostatitis and the like⁵

Adjustment of Height of Siphon Curve

The proper height of the siphon curve varies with the stage the bladder has reached in its recovery. As pointed out in greater detail below, bladders

associated with significant injuries of the spinal cord or cauda equina pass through four such stages. These are recognizable only by cystometry and vary unpredictably in duration.

Immediately after injury the bladder is atonic. For this stage the siphon curve should be set at 1 or 2 cm above the bladder level. Recovery progresses through the stages of autonomicity and hypertonicity to the reflex or automatic phase. The siphon curve should be set at 2 to 5 cm above the bladder level for the autonomous, at 15 to 18 cm for the hypertonic and at 10 to 12 cm for the reflex bladder. If the occasion arises—for example, in a patient who is completely unconscious following a severe head injury—when tidal drainage must be used in connection with a normal bladder the siphon curve should be set at 10 to 12 cm above the bladder level, as in the reflex or automatic bladder.

CYSTOMETRY

By cystometry it is possible to determine what the functional activity of the bladder is at the time the cystometrogram is made. As a method of examination it does not pretend to be and cannot be more than relatively exact. If the cystometer and the method of using it approximate as closely as possible the normal physiologic process of filling the human bladder, however, this relative exactitude is sufficient for the purpose at hand. I believe this requirement to be of considerable importance particularly in view of the fact that a number of authors⁷⁻¹⁰ have advocated cystometric methods that do violence to this concept.

A normal bladder that is normally innervated receives urine from the ureters constantly and in small increments.¹¹ The increments are of the order of magnitude of drops. They never, under any circumstances, reach individual amounts of, for example, 10 cc at a time. An increment of 25 or 50 cc is physiologically fantastic. The bladder wall, certainly in human beings and probably also in such animals as the dog and cat, reacts in a physiologically normal manner to any normal increase in content. The musculature can and will react also to the admission at one time of larger amounts of fluid but not in the physiologic manner. Inferences regarding the normal activity of the bladder as the result of such abnormal stimuli are not justified and cannot be accepted as evidence for or against any conclusions other than that a purely experimental procedure that has no physiologic basis produces a certain type of muscular reaction. Conclusions based on such cystometric methods—as advocated by Rose,⁷ Voris and Landes,⁸ Langworthy and Hesser⁹ and Langworthy, Kolb and Lewis¹⁰—cannot therefore be accepted as explanations of normal bladder physiology. All the authors cited advocate cystometric methods in which unit increments of 25 or 50 cc of fluid are repeatedly introduced into the bladder.

The lethal effect of sepsis on the recovery of skeletal neuromuscular activity that has been previously altered by damage to the central nervous system is well recognized. The neuromuscular mechanism of the bladder can be shown to respond in the same way to this same complication.^{12,13} The deleterious influence of hypoproteinemia on the healing of bedsores, with resultant acute and chronic sepsis, was called attention to in 1940.¹⁴ Many writers have since confirmed this statement, and it is generally acknowledged that proper nutrition is essential for the cure of infection, as well as for the recovery of function and the well-being of patients with cord injuries. Experience with such patients in the Army¹⁵ and elsewhere merely emphasizes this fact. Many of Head's¹⁶ cases in which conclusions were drawn concerning bladder activity were palpably the result of chronic sepsis and probably also of hypoproteinemia. These data can no longer be ignored, and neurophysiologists, such as Fulton,¹⁷ should revise accordingly their concepts of bladder function in man. Interpretation of cystometric evidence without a knowledge of these and other variables is also impossible, and conclusions drawn therefrom are therefore untenable.

Technic

The observations reported herewith have been made with a cystometer that is to all intents and purposes a U tube¹⁸ (Figs 2 and 3) connected with the contents of the bladder by an unbroken column of fluid. Both ends of the U are open. When a cystometrogram is being made, a standard fill of 400 cc is used. This fluid is introduced into the bladder at a steady rate of not more than 90 drops a minute. Experiments have demonstrated that this is slow enough to reproduce the physiologic response to the normal filling that takes place by way of the ureters. In every case a catheter that is not of the Foley type is fastened in place in the bladder. The aspirator bottle in either type of tidal-drainage apparatus is replaced by a cylindrical glass container graduated in 25-cc amounts. The siphon curve is raised to 50 cm above the bladder level. The cystometer is first filled with an appropriate bland fluid, and all air bubbles are evacuated, after which it is closed off at the point of attachment to the catheter by a clamp. The bladder is then emptied, the catheter is attached to the cystometer, and the clamp is loosened. The compression clamp between the cylindrical container and the airtight Murphy dropper having been opened so that fluid flows at the proper rate of 90 drops a minute and the meniscus in the cystometer tube having been adjusted to the bladder level by the addition of any necessary fluids, it is possible to fill the bladder and read the intravesical pressure simultaneously. The pressure is read in connection with the height above zero of the meniscus in the cystometer tube. The amount of fluid that is in the bladder at any one

is determined by reading the fluid level in the cylinder. Changes in this level of as little as 1 cc. can be approximated with sufficient accuracy to justify recording. Each change in intravesical pressure—whether up or down—that is noted on the cystometer is recorded and opposite placed the amount of fluid that has run over into the bladder up to that point. An additional notation is made whenever there is leakage about the catheter whenever the cystometer tube or siphon curve flows. Recordings are continued until 400 cc of fluid has been run through the apparatus, unless there is reason to fear reflux up the ureters, in which case smaller amounts and lower pressures are used. The catheter is then disconnected from the apparatus and the bladder is allowed to empty itself with the open end of the catheter held at zero level. This urine is collected and measured. When this process is completed the catheter is lowered and any residual urine that flows out by siphonage is also collected and measured. The operator will then have two parallel columns of figures (one being intravesical pressure readings and the other intravesical cubic centimeters of fluid), as well as the amounts of the residual urine and the urine in the bladder at the close of the procedure.

Interpretation

From these data necessary information regarding bladder function can be obtained. The presence of emptying contractions is indicated when the intravesical pressure reaches or exceeds 50 cm of water, when there is leakage around the catheter or when either the cystometer or the siphon curve overflows. By noting the amount of fluid that has been delivered to the bladder between each succeeding emptying contraction, it is possible to determine the periodicity and frequency with which the contractions occur.

The curve of basic tonus can also be observed. By subtracting the lowest intravesical pressure from the highest and noting the amount of fluid that has gone through the apparatus, a fairly accurate estimate of the shape of the curve of basic tonus can be obtained. This is a function of the irritability of the detrusor muscle.

The minimal capacity of the bladder is the amount of fill that has collected between the first and second emptying contractions.

The residual urine is best expressed in percentage of fill. To obtain this the amount of residual urine is divided by the sum of the amount of fill (usually 400 cc) and the amount of urine collected from the bladder at zero level at the close of the procedure.

Temporary elevations of intravesical pressure that neither rise to the height of an emptying contraction nor cause leakage about the catheter are aborted emptying contractions.

The presence of an anal or bulbocavernosus reflex is determined last of all. The test is made by prick-

ing either the perianal region or the glans penis with a pin and observing whether or not there is a reflex contraction of the anus. If there is, the reflex is normal, if there is not, it is abnormal.

By plotting the two columns of figures (centimeters of intravesical pressure and cubic centimeters of intravesical fluid) on co-ordinate paper, a graph of the bladder activity during this experimental fill can be drawn. This is not necessary for adequate interpretation, however. Figure 4 depicts the composite result of cystometric data collected as described above from observations on the bladders of normal persons.

Material

This type of cystometer was used to make observations on 50 persons of varied ages and of both sexes who had completely normal nervous systems and genitourinary tracts, 12 otherwise normal women before and after complete presacral-nerve resection for dysmenorrhea, 22 patients with anatomic cord transections, 16 patients with physiologic cord transections, 35 patients with nontransecting cord lesions, 8 patients with injuries to the sacral cord and conus and 20 patients with various degrees of injury to the cauda equina. In addition, there were 50 patients with less severe cord injuries in whom tidal drainage was used for so short a time that the cystometric observations were not considered useful for the purposes of this paper.

The 101 patients in the selected group with injuries to the cord were, for the most part, studied cystometrically at weekly intervals from the time of admission to the hospital until discharge. Correlation was made between the cystometrograms and the presence and condition of any pressure or bedsores that were present. The trend of the serum protein, as measured by weekly observations of the blood level in milligrams per 100 cc, was constantly observed, and a tendency to fall was forestalled, if possible, by a high-protein reinforced diet and if necessary by the transfusion (multiple when indicated) of whole blood. Sepsis of the genitourinary tract was so insignificant a factor¹⁹ after tidal drainage was used efficiently that it had little or no influence on the observations. Other sepsis and toxemia were given due weight when present. At a conservative estimate, over two thousand cystometrograms on 213 patients with various degrees of injury to the cord, conus and cauda equina have been done in the past twelve years. There can be no doubt that the cystometry has complied with the requirements set down above as minimal.

Observations

In addition to observations that have been made on normal human beings, others have been collected from the human analogue of the spinal animal and under physiopathologic conditions that have not

associated with significant injuries of the spinal cord or cauda equina pass through four such stages. These are recognizable only by cystometry and vary unpredictably in duration.

Immediately after injury the bladder is atonic. For this stage the siphon curve should be set at 1 or 2 cm above the bladder level. Recovery progresses through the stages of autonomicity and hypertonicity to the reflex or automatic phase. The siphon curve should be set at 2 to 5 cm above the bladder level for the autonomous, at 15 to 18 cm for the hypertonic and at 10 to 12 cm for the reflex bladder. If the occasion arises—for example, in a patient who is completely unconscious following a severe head injury—when tidal drainage must be used in connection with a normal bladder the siphon curve should be set at 10 to 12 cm above the bladder level, as in the reflex or automatic bladder.

CYSTOMETRY

By cystometry it is possible to determine what the functional activity of the bladder is at the time the cystometrogram is made. As a method of examination it does not pretend to be and cannot be more than relatively exact. If the cystometer and the method of using it approximate as closely as possible the normal physiologic process of filling the human bladder, however, this relative exactitude is sufficient for the purpose at hand. I believe this requirement to be of considerable importance particularly in view of the fact that a number of authors⁷⁻¹⁰ have advocated cystometric methods that do violence to this concept.

A normal bladder that is normally innervated receives urine from the ureters constantly and in small increments.¹¹ The increments are of the order of magnitude of drops. They never, under any circumstances, reach individual amounts of, for example, 10 cc at a time. An increment of 25 or 50 cc is physiologically fantastic. The bladder wall, certainly in human beings and probably also in such animals as the dog and cat, reacts in a physiologically normal manner to any normal increase in content. The musculature can and will react also to the admission at one time of larger amounts of fluid but not in the physiologic manner. Inferences regarding the normal activity of the bladder as the result of such abnormal stimuli are not justified and cannot be accepted as evidence for or against any conclusions other than that a purely experimental procedure that has no physiologic basis produces a certain type of muscular reaction. Conclusions based on such cystometric methods—as advocated by Rose,⁷ Voris and Landes,⁸ Langworthy and Hesser,⁹ and Langworthy, Kolb and Lewis¹⁰—cannot therefore be accepted as explanations of normal bladder physiology. All the authors cited advocate cystometric methods in which unit increments of 25 or 50 cc of fluid are repeatedly introduced into the bladder.

The lethal effect of sepsis on the recovery of skeletal neuromuscular activity that has been previously altered by damage to the central nervous system is well recognized. The neuromuscular mechanism of the bladder can be shown to respond in the same way to this same complication.^{12,13} The deleterious influence of hypoproteinemia on the healing of bedsores, with resultant acute and chronic sepsis, was called attention to in 1940.¹⁴ Many writers have since confirmed this statement, and it is generally acknowledged that proper nutrition is essential for the cure of infection, as well as for the recovery of function and the well-being of patients with cord injuries. Experience with such patients in the Army¹⁵ and elsewhere merely emphasizes this fact. Many of Head's¹⁶ cases in which conclusions were drawn concerning bladder activity were probably the result of chronic sepsis and probably also of hypoproteinemia. These data can no longer be ignored, and neurophysiologists, such as Fulton,¹⁷ should revise accordingly their concepts of bladder function in man. Interpretation of cystometric evidence without a knowledge of these and other variables is also impossible, and conclusions drawn therefrom are therefore untenable.

Technic

The observations reported herewith have been made with a cystometer that is to all intents and purposes a U tube¹⁸ (Figs 2 and 3) connected with the contents of the bladder by an unbroken column of fluid. Both ends of the U are open. When a cystometrogram is being made, a standard fill of 400 cc is used. This fluid is introduced into the bladder at a steady rate of not more than 90 drops a minute. Experiments have demonstrated that this is slow enough to reproduce the physiologic response to the normal filling that takes place by way of the ureters. In every case a catheter that is not of the Foley type is fastened in place in the bladder. The aspirator bottle in either type of tidal-drainage apparatus is replaced by a cylindrical glass container graduated in 25-cc amounts. The siphon curve is raised to 50 cm above the bladder level. The cystometer is first filled with an appropriate bland fluid, and all air bubbles are evacuated, after which it is closed off at the point of attachment to the catheter by a clamp. The bladder is then emptied, the catheter is attached to the cystometer, and the clamp is loosened. The compression clamp between the cylindrical container and the airtight Murphy dropper having been opened so that fluid flows at the proper rate of 90 drops a minute and the meniscus in the cystometer tube having been adjusted to the bladder level by the addition of any necessary fluids, it is possible to fill the bladder and read the intravesical pressure simultaneously. The pressure is read in connection with the height above zero of the meniscus in the cystometer tube. The amount of fluid that is in the bladder at any one

patient can tell whether his bladder is empty and needs to be emptied may be misleading to determine at what point desire to void occurs and at what point pain occurs. The first is a function of the patient's ability to inhibit emptying contractions and is affected by such a wide variety of stimuli — varying from inability to urinate while in bed or in the presence of another person to the effect of a total

those advanced in the two previous papers^{5, 20} of this series are compiled from observations made on human beings only. Lesions of the spinal cord have been verified by operation, autopsy and clinical observations carried on for a sufficiently long time to establish a stabilized end point and the diagnosis beyond any question of doubt. Cystometrograms have been made in accordance with the physiologic requirements outlined above and by a wide variety

FIGURE 5 The Graphs of Atonic Bladders

The upper one was made ten hours after a cervicodorsal hematomyelia, and the lower one forty-three days after a cervical hematomyelia. In the latter case the atonicity occurred following the development of a major infection.

d transection — that conclusions based on it are not only unreliable but may lead one astray. The sensation of pain in the bladder wall, if present, means that the organ is being dangerously over-stretched. If not present, it may mean the same thing only this time that the danger will be greater

of observers. They strongly suggest the following conclusions. When a human spinal cord is transected either anatomically or physiologically below the fourth cervical and above the second sacral segment, in addition to a complete anesthesia and a total loss of all voluntary motor control below the

FIGURE 6 The Graph of an Autonomous Bladder

This measurement was made twenty-three days after concussion with transection of the dorsal cord. Aborted emptying contractions are present.

because it is unrecognizable. In addition, it may be pointed out that any interpretations of the physiology of micturition that depend even in part on observations made by the patient and that require an intact nervous system are valueless in the face of an anatomically or physiologically transected spinal cord. The observer who is accustomed to rely on such observations in his clinical work will find himself without them and at a loss in the type of case in which he needs cystometrography most.

The interpretations presented herewith as well as

level of cord injury, the immediate response of the bladder is to become atonic (Fig 5). The detrusor muscle does not contract at all. The internal sphincter closes tightly and remains closed and unresponsive to any physiologic stimuli during this phase. The external sphincter is relaxed, and the anal and bulbocavernosus reflexes are abolished. Any emptying that occurs is only the result of leakage through the contracted internal sphincter and takes place because of the elasticity of the bladder wall and not by virtue of any contractile effort on its part. The

previously been duplicated. The effects of sepsis, hypoproteinemia, avitaminosis, anemia, physical activity and the like have all been evaluated in relation to the problems of the physiology of micturition and the recovery of the bladder function in these patients. Complications that under other conditions and in other similar series of observations have altered, made unreliable and in some cases vitiated the observers' conclusions either have been recognized as untreatable and the conclusions discarded

the curve of basic tonus, varying from the flat curve of atonicity to the steep gradient of hypertonicity—the former may be present in normal bladders and will be present between the emptying contractions in reflex bladders, and the latter occurs as described below, an anal or bulbocavernosus reflex, which is present only in the absence of spinal shock and when the internal pudic nerve and its spinal-cord connections are intact, indicating either normal voluntary or abnormal involuntary reflex control of the ester

FIGURE 4 Composite Cystometric Data Relative to the Normal Bladder
On the abscissas are recorded cubic centimeters of fill, and on the ordinates centimeters of pressure

or have been successfully treated and brought to an end before conclusions were drawn. In the course and partly as the result of these observations it became apparent that in interpreting this group of cystometrograms certain information was essential, other data were not essential but possibly useful, and some were misleading in an estimation of the degree of recovery of bladder function. The essential cystometric information is as follows: the presence of emptying contractions—only normal or reflex bladders develop the classic emptying contractions,

nal urethral sphincter, and the capacity of the bladder, which will be a minimal figure varying from the large amount that is limited only by the elasticity of the bladder wall and is collected in atonic bladders to the small amount that is present in bladders that are hypertonic, hypertrophied and shrunken or infected—a minimal capacity below 150 cc is abnormal.

It is useful to know whether or not aborted emptying contractions are present, how much residual urine (expressed in percentage of fill) is present, and

the control that is apparent later as normal micturition. Under certain conditions, however, this inhibitory ability can be lost again, the bladder reverting to reflex activity in the absence of any physical impairment of its nervous connections. Emotional stress, such as extreme fear or bodily harm, may so relax the inhibitory control exerted by the higher centers that the person experiencing such an emotion finds himself — if the bladder has not been emptied just previously — voiding urine once the danger is passed. I am inclined to think that this was not an infrequent experience during the worst London air raids. Coma, if suffi-

cient to produce overflow incontinence is the result of an inhibitory effect exerted to the point of overdilatation and caused by a subconscious realization that bed is not the place in which to urinate. The restlessness and struggles to get out of bed that persist until a urinal is put in place and the bladder emptied completely of a large amount of urine, only to be followed by a period of quiet or sleep, afford verification of this phenomenon. Indeed, the change from the periodic urination of large amounts that is characteristic of reflex micturition to the irregularly spaced, frequent discharge of the small amounts of overflow incontinence is often an early and always a reliable sign

FIGURE 8 *The Graph of a Reflex Bladder*

This measurement was made seven months after concussion with transection of the dorsal cord

ciently deep, produces the same chain of events, if it is less profound, and even though the victim is out of conscious touch with his surroundings, inhibitory control continues to be exerted, however, and the bladder is prevented from emptying. Convulsive seizures with the profound coma and loss of "sphincter control" of grand mal, on the one hand, and the momentary unconsciousness without soiling of the petit-mal attacks, on the other, as well as the variations between, illustrate these phenomena in all degrees.

Cerebral injuries, although not so clear cut on account of the associated central-nervous-system damage, provide similar examples. The deeply comatose patient empties the bladder of large amounts of urine at rare, fairly evenly spaced intervals. The bladder functions on a pure reflex plane, empties completely with each emptying contraction and is deprived of all inhibitory influences. As the condition improves and the coma lessens, the type of micturition changes, and the patient begins to pass small amounts of urine often and at irregular intervals. Catheterization easily demonstrates that

of the lessening of unconsciousness and an improvement in such a patient's condition and vice versa.

Reflex bladder activity is also a function of the anatomically and physiologically transected cord. Under such conditions, it is the best end result that can be attained, and bladder training as described below is merely a method of making practical use of this phenomenon. It is this activity that has been referred to in the past as the "automatic bladder." In nontransecting injuries, it is not and should not be considered an end result. In these injuries the activity is analogous to that of the reflex bladder of the normal infant. Further training enables the patient to regain the normal inhibitory control just as the child does as he grows older. In this reflex stage the detrusor muscle contracts reflexly and completely in response to the sensory stimulus provided by the stretch of a critically filled bladder. During the fill and before the accumulation of this critical amount of urine, any emptying contractions are aborted in favor of a stretch reflex and consequent increase in the cubic capacity of the organ. The internal sphincter remains closed until the emptying

bladder capacity is limited only by this elasticity. Bladders that have advanced beyond this stage toward recovery will regress to it in the presence of spinal shock, exhaustion, sepsis, toxemia and hypoproteinemia (Fig 5). The length of time that a bladder remains in this atonic stage depends on these complications, the severity of the injury and the efficiency of the treatment.

The next stage toward recovery is characterized by the development of ineffective aborted emptying contractions (Fig 6). The level of basic tonus is slightly higher than that in an atonic bladder. The internal sphincter is tightly closed and only partially

but not proved that the neural control is exerted, way of an intramural autonomous plexus.

The third stage toward recovery is the hypertonic. This is characterized by something approximating tetany of the detrusor muscle (Fig 7). It is in a nearly constant state of contraction, the curve of basic tonus is steep, and the intervals between emptying contractions are extremely short. The internal sphincter reacts physiologically, opening with each emptying contraction and closing in the intervals. The external sphincter responds reflexly, and the anal and bulbocavernosus reflexes are present. The bladder capacity as measured by the amount

FIGURE 7 The Graph of a Hypertonic Bladder

This graph was made five days after compression of the lumbosacral cord

opens in response to the inefficient aborted emptying contractions of the detrusor muscle. The bulbocavernosus and anal reflexes may return. There are no emptying contractions. This stage may be extremely short and will be missed if cystometrograms are not made frequently enough. The bladders discharge small amounts of urine frequently. Their capacity is at first large but becomes increasingly smaller as hypertrophy of the muscular wall develops. The bladders regress to the atonic stage for the reasons given above. The length of time that the bladder remains in this stage again depends on any complications and the efficiency of treatment, but not on the severity of the injury. This is the autonomous stage, so called because it is believed

of urine stored between emptying contractions is small. This stage is often of short duration; either it regresses toward atonicity or progresses to the reflex stage. An acutely infected but otherwise normal bladder may give a cystometrogram that is indistinguishable from one made during this stage. Normal uninfected bladders exhibit these characteristics just before emptying if they are distended beyond normal limits but have not been so stretched as to have become atonic (Fig 4).

The final stage is that of the reflex bladder (Fig 8). In small children who have not yet learned to obey the dictates of civilization this represents normal bladder activity. Increase in capacity and training in the inhibition of emptying contractions pro-

he bladder concerns the transmission of pain that organ appears to be confirmed

BLADDER TRAINING

Bladder training should be necessary only in patients with anatomically or physiologically transected cords. It will be effective only if the patient has an intelligent interest in the problem and co-operates. If the bladders have been properly cared for from the time of injury, such training is not necessary with nontransecting cord injuries. It is ineffective in patients with destructive lesions of the spinal cord or roots and the parasympathetic centres. It cannot be imposed on and is not successful in any patient who is mentally deficient or inco-operative or who has a suprapubic or perineal stoma, bladder obstruction from any cause, an infected bladder, vesical or renal calculi, pyelitis or pyelonephrosis, general sepsis, toxemia, exhaustion, debilitation, hypoproteinemia, avitaminosis, large unhealed bedsores and the like. The bladder activity must be of the reflex type, and the bladder capacity at least 200 cc, in patients with an active mass reflex the lower half of the abdominal wall must have been paralyzed either because of approximate thoracic-root destruction as part of the injury or following operative bilateral anterior dorso-lumbar rhizotomy. To prevent genitourinary infection the fluid intake must not be allowed to fall below 3600 cc in twenty-four hours during the period of training. Bladder training is much easier when the patient is ambulant in splints and with the aid of crutches, but its initiation should not be postponed on that account. The patient must have sufficient use of his hands to clamp and unclamp the catheter, must have a watch, must understand the elements of the problem he is faced with, must be co-operative and must be willing to assume full responsibility for the solution of that problem. With these requirements met, all that is necessary is patience and perseverance on the part of both the patient and the doctor.

Control of micturition is possible in the presence of a transected cord because the bladder, if not otherwise altered, can be distended to a point where it contains from 200 to 400 cc of urine before emptying and because an emptying contraction can be initiated as a reflex response to appropriate sensory stimuli at any time previous to that point. By appropriate regulation of the fluid intake, the time that elapses before this amount is collected in the bladder can also be predetermined. By emptying the bladder reflexly under controlled conditions immediately before the contents reach the critical level, soiling with urine at unexpected times can be prevented.

Technic

The first stage in the training is to condition the bladder so that it will distend to the point where it

holds 200 cc or more without developing an emptying contraction. This phase can and should be started while the patient is still in bed and as soon as the bladder activity has become reflex in type. To do this, the catheter is left in place but disconnected from the tidal-drainage apparatus and clamped off for an hour and a half at a time. At the end of each of these periods the catheter is opened, the open end placed so as to empty into a urinal and the bladder made to contract by appropriate reflex stimulation such as massage of the abdomen, scratching of the thigh or any similar procedure that is effective. Forcible expulsion of the contents by pressure through the abdominal wall should not be practiced under any circumstances. The fluid intake is adjusted so that no fluid is taken between 7:00 p.m. and 7:00 a.m. During the other twelve hours 300 cc should be ingested every hour, preferably on the hour. This fluid intake remains the same throughout the training period and thereafter until full adjustment and control are obtained. The patient should be held responsible for draining his own bladder at proper intervals during the day. At night the catheter should be attached to the tidal-drainage apparatus. After he is able to go for a week without leakage between emptyings, the interval should be increased to two hours. The process is repeated until the same requirement can be successfully met. After this, the interval is increased to two and a half hours and then to three hours. The greatest difficulty is usually encountered in making the change from an hour and a half to two hours. If leakage occurs at that time or at any other change, the patient should be put back on the next shortest interval for another week or so and the shift upward tried again.

When the patient can successfully manage a three-hour interval without leakage, he should be taken off tidal drainage at night. Instead he should be awakened and made to empty the bladder every two hours until a week has passed without leakage and subsequently every three hours. He will then be able to retain the bladder contents for three hours at a time without leakage day and night, but the catheter will still be in place. The activity of the detrusor muscle has been conditioned, but not the sphincters. To attain that end, the catheter should be removed entirely and the time interval between emptyings cut back again to an hour and a half. The intervals are then increased as indicated above, but without the catheter. It is during this stage that obstruction by a spastic or hypertrophied internal sphincter becomes evident if it exists. Such a condition occasionally requires resection, but this should not be done until a serious effort has been made and enough time allowed to elapse for the sphincter to correct its own spasticity. Any other obstruction to emptying must be corrected at once and before the training can be continued. It is about this time also that the patients begin to be ambulant. This

contraction takes place, when it opens and permits urine to escape into the posterior urethra. This, in turn, acts as a sensory stimulus that causes the external sphincter to relax reflexly from its previously contracted closed position. The bulbocavernosus and anal reflexes are present. If the cord injury is nontransecting the patient also has the ability to relax and contract voluntarily the external sphincter. If the injury is a transecting one, this voluntary control is permanently lost. If the bladder has not been allowed to shrink during the early stages of its recovery from atonicity, its critical capacity varies from 200 to 400 cc or more. When it does empty, all the contents are expelled. Reflex emptying in cases of transected cord may also be initiated — regardless of the amount of the contents — by contraction of the abdominal muscles, stimulation of the abdomen, thigh and other areas of the leg, catheterization, movement of the bowels and change in position. Facilitation of micturition as a part of the "mass reflex" described by Head¹⁶ is, according to my observations, no more than an indirect and coincidental effect. In patients whose abdominal musculature has been paralyzed because of the destruction of the lower dorsal roots but in whom the mass reflex is typical and active, there is no such facilitation. I have seen two such cases. Also, as noted in a previous paper,²⁰ in patients in whom the mass reflex has been inactivated by anterior rhizotomy, facilitation of micturition is still present on a reflex level in response to stimulation of the skin of the thigh and an increase in intra-abdominal pressure, as well as to intravesical stimulation acting alone and without any external aid and caused by the collection of a critical amount of fill within the bladder. I have had experience with 10 such cases. Regression toward atonicity takes place in the presence of infection, toxemia, exhaustion, a major operative procedure, hypoproteinemia and so forth. A decrease in capacity and hence an increase in the number of emptying contractions develop in the presence of cystitis, vesical calculi and prolonged suprapubic drainage. Urinary retention despite the presence of otherwise efficient emptying contractions has been shown to be caused by hypertrophy or fibrosis²¹⁻²⁴ with a pseudo-median-bar formation of the internal sphincter. Although the evidence is not conclusive, it is probable that this retention has its origin in injudicious early treatment of the bladder and is a complication of too prolonged and constant catheter or suprapubic drainage. It has occurred only twice in my series of 40 cases with anatomic and physiologic transections. One was in a patient who had been subjected to suprapubic drainage for five months followed by catheter drainage for the same length of time. The other had catheter drainage for three months following the accident. For two years and nine months thereafter he had no bladder treatment of any kind. Many of the other patients in this group, however,

had as long or longer periods of suprapubic or catheter drainage without the development of this complication.

Destructive lesions that are complete and involve the sacral segments or roots or the parasympathetic plexuses, and hence completely denervate the bladder as far as its central connections go, force the bladder to depend on the intramural plexus for neuromuscular control. This ability develops after the bladder has recovered from the atonic stage. The resultant bladder activity duplicates that described above under the term "autonomous bladder" (Fig. 6). This is the best physiologic end result that can be obtained in such cases. Because of the total denervation it is impossible to impose bladder training on these patients. That does not mean, however, that the patients must accept a contracted bladder that will hold only 30 or 50 cc and that leaks continually constantly. Even in the face of total denervation, the bladder capacity can be maintained at normal by the prompt use of tidal drainage in the preconvalescent bed stage. When the patient is ambulant, unailing twenty-four-hour control can be established if the patient continues to wear an indwelling catheter. During the day the catheter is kept closed by a clamp except when the bladder is emptied at intervals of three or four hours. During the night, while the patient is in bed, the catheter is opened and attached to a tidal-drainage apparatus with the siphon curve set at 10 to 12 cm. The bladder wall is thus kept from hypertrophy and contraction, and the patient is enabled to keep himself dry and clean at all times. The catheter is removed, cleaned, resterilized and replaced aseptically once a week, and the apparatus taken down, cleaned, resterilized and reassembled after the same interval. Solution M or Solution G⁶ is used as an irrigating fluid. Any person of ordinary intelligence can without difficulty be taught the proper care of himself and this apparatus.

Impulses reaching the bladder by way of the sympathetic as distinguished from the parasympathetic and somatic nervous systems have no influence on the function of storage or discharge. This was first enunciated by Denny-Brown and Robertson.²⁵ Through the kindness of Dr. Frank A. Pemberton I was enabled to make preoperative and postoperative cystometric observations on 12 otherwise normal women whose presacral plexuses were totally removed because of dysmenorrhea. In every case the bladder activity was unaltered following the sympathetic denervation. Similar findings have been reported by Marshall and Kennedy.²⁶ In the light of this evidence, Learmonth's²⁷ conclusions, and Fulton's¹⁷ acquiescence in them, regarding the antagonistic control of bladder activity so far as it refers to the sympathetic-nervous-system innervation of the bladder, cannot be accepted any longer. Denny-Brown and Robertson's²⁵ original contention that the effect of the sympathetic nervous system

not investigated but not even considered, this is permitted to remain undisturbed only to minimize and produce fibrotic adhesions, which compress and deform the cauda equina.²⁸ Varied symptoms of radiculitis develop, the usual ones being alone or in combination with the type of urinary difficulty described above. Clinical evidence suggests that to correct the bladder symptoms the radiculitis must be relieved and the bladder stretched if it has shrunk. The first is accomplished by a decompressive lumbar laminectomy in which the five laminae overlying the cauda equina are removed, the dura opened for the full length of the wound and any neurolysis that may be possible carried out. The wound is then closed without drainage and without closing the dura. Preoperative investigation of the dynamics of the spinal cerebrospinal fluid is essential and usually reveals a partial and often a complete dynamic block. The patient is put on tidal drainage adjusted to meet the requirements of the cystometric findings and to stretch the bladder if necessary. This is continued until the capacity has been raised to over 200 cc, after which bladder training as described above is instituted. Following this procedure, which has been carried out in 14 such patients, all of whom were unemployable on account of their urinary difficulty, all but 2 have returned to regular employment and all are free of urinary symptoms.

SUMMARY

Two types of apparatus for tidal drainage are described, and directions given for their construction. The physiology of micturition is briefly discussed. A method of cystometric examination of bladder function in normal bladders and in those rendered abnormal by spinal-cord, conus and cauda-equina injuries is described, and an interpretation of the findings is given. A method of bladder training that will permit unfailing twenty-four-hour control of urination, even in the face of an anatomic cord transection or total denervation of the viscus, is discussed in detail.

change from the recumbent or sitting to the erect position also alters the bladder activity. It is often found that control of micturition, which is entirely satisfactory with the patient erect, fails miserably when he returns to bed. Increased exercise, such as greater agility in using crutches, may also cause temporary intermittent leakage. Persistence in practice and repetition of the earlier training stages, even perhaps to the extent of catheter replacement, will overcome all these difficulties sooner or later, particularly if an increase in ambulation is insisted on. It is also helpful if the patient makes a practice of using the toilet rather than the urinal at each bladder emptying. The position of the body and possibly also the psychology of urinating in such surroundings appears to be conducive to greater efficiency in micturition. In especially difficult cases much help can often be obtained by making the patient keep his own intake and output chart. This should include a time schedule as well.

Complications

Once the patient has reached the stage where he can go for three hours without urinating or leaking during both day and night, he can be allowed to go through the night without being awakened at all or, at most, only once. The daytime interval can also be extended from half an hour to an hour if the need arises. Under no circumstances should the interval between drainages be shortened — such a procedure will quickly cause regression of bladder function. Any unexpected break in efficiency should lead to prompt investigation of the cause. One of my patients was found to have a vesical calculus that had been entirely asymptomatic until the patient was well past the first stages of ambulation. Sudden inability to control micturition in another case was found to have been caused by a small papilloma that had developed without my knowledge and in spite of previous cystoscopic examinations while the patient was under treatment for a cord injury. Removal of the stone and fulguration of the papilloma permitted both patients to regain twenty-four-hour control of micturition.

Successful bladder training can be acquired by any patient with a transected cord if the requirements discussed above are met. It is acquired much more easily and rapidly, however, if the bladder is kept in a state of physiologic normalcy during the immediate post-injury convalescence by the proper use of tidal drainage supplemented by the necessary number of cystometrograms. As pointed out above, an automatic bladder, although better than a contracted or permanently drained bladder, cannot be considered a satisfactory end result. It is merely a preliminary stage in the return of bladder function and should be recognized as a condition that can be transmuted into unfailing twenty-four-hour control of micturition if the physician is alert

to the possibilities and the patient intelligent co-operative.

Patients with denervated bladders (destructive lesions of the sacral cord or roots or parasympathetic plexuses) can have the same control but must be willing to wear a catheter constantly and to maintain tidal drainage at night. They are trained in the manner described above to increase the interval between bladder drainages from an hour and a half to three hours, except that they never reach the stage of training without catheters and that they are not awakened at night. It is possible that resection of the internal sphincter²¹ will eventually prove to be the solution that will permit removal of the indwelling catheters and abandonment of the tidal-drainage apparatus in these cases.

No satisfactory method of treating the urinary difficulties of patients with paralyzed hands has been evolved, other than to have an attendant open and close the catheters during the first part of the training period. Manpower shortage has made this impractical, but if that difficulty can be overcome, there is no reason why such patients should not eventually attain bladder control once the catheters can be removed. After that, the reflex emptying that follows sensory stimuli set up by scratching the abdomen or thigh will be within the scope of their limited activities. Fortunately, these cases are rare, because patients with transections of the middle and lower thirds of the cervical cord — whether anatomic or physiologic — rarely survive long enough to reach the stage where bladder training is indicated, and if they do, it is of little practical value to them because of the impossibility of ambulation. So long as they are bedridden, they do better on tidal drainage. Patients with nontransected cases with hand paralysis traceable to cord changes associated with hematomyelia will have normal bladder activity if their bladders are properly treated from the start. The only problem is to obtain urinals that they can use when necessary. With normal control of micturition, accidents can usually be avoided because of the leeway permitted by virtue of the ability to inhibit an emptying contraction for a reasonable and possibly a considerable period.

Patients with cauda equina injuries that do not denervate the bladder may nevertheless have sufficiently disabling bladder symptoms to prevent a normal social and work life. Cystometrically, the only variation from normalcy is a decreased capacity and evidence of hypertonicity in that emptying contractions develop more frequently than normal and the curve of basic tonus is steeper than normal. The bladder symptoms are usually extreme urgency, frequency, dribbling and unexpected major leakage. In my experience all these patients have sustained such injuries in civil life. There has been a major fracture of a lumbar vertebra with the escape of quantities of free blood into the lumbar subarachnoid space. Because this possibility is usually no

underwent a second operation, during which 83 of tissue was removed. The postoperative course difficult, with true thyroid storm, and again the ase persisted until the final operation, when 50 of tissue was removed. Following this, except a transient unilateral vocal-cord paralysis, this patient made a complete recovery.

Thompson and his colleagues^{2,3} have presented much of the adequate data on recurrent and persistent hyperthyroidism, reporting an incidence of operative thyrotoxicosis in 19.5 per cent of cases at the Massachusetts General Hospital and in 17.5 per cent at the Presbyterian Hospital in Chicago. Data from the Massachusetts General Hospital indicate that this rather high incidence was attended by a low incidence of true myxedema (1 per cent). The studies made in the series at the Peter Bent Brigham Hospital reveal that 83 per cent of patients avoided recurrent or persistent thyrotoxicosis.

The figures cited above indicate that the results reported from the Peter Bent Brigham Hospital are probably representative of those to be expected from other hospitals where general surgery is practiced. They are also in accord with the data concerning postoperative thyrotoxicosis gathered by Fulton, Smith and Cutler⁴ in this hospital in 1938.

Four patients died as a result of the operation. The ages ranged from forty to forty-nine years. Two deaths were due to postoperative thyroid storm, and one to hemorrhage into the wound with cessation of respiration. Each of these patients had responded favorably to treatment with iodine and bed rest prior to operation. The fourth fatal case occurred in a woman who refused further treatment after an adequate response to iodine had been obtained. She continued to take iodine for ten months after discharge and lost 35 pounds in weight. After readmission to the hospital, where iodine was withheld for three weeks, she failed to respond when it was readministered. The patient died on the operating table. Microscopically, the thyroid gland showed "diffuse hyperplasia with iodine involution," and in addition, a diagnosis of acute rheumatic fever was made at autopsy. This case is an example of the recognized clinical phenomenon that surgery is safest when it follows iodine therapy given patients for the first time, or when such patients have been untreated by iodine for at least six to eight weeks before operation.

A comparison of these results with those reported from other institutions is of interest. Mortality statistics in thyroidectomy for Graves's disease vary greatly, ranging as high as 13.1 per cent, as reported by Thompson, Taylor, and Meyer⁵ at the Cook County Hospital. Maes, Boyce, and McFetridge⁶ reported a mortality of 10.6 per cent at Charity Hospital in New Orleans. Among the lowest figures is that of 0.63 per cent given by Clute.⁷ It appears that the surgical mortality in Graves's disease at the Peter Bent Brigham Hospital (2.7 per cent) is

in the lower range for hospitals in which general surgery is practiced.

A final compilation may be made by a division of the cases into two groups — those with satisfactory and those with poor results.

To the 80 patients who experienced a return to complete good health may be added the 18 patients with hypothyroidism, since all ultimately became asymptomatic through the use of thyroid. In addition, the persistence of exophthalmos should not be considered a poor result, and 10 patients in whom this occurred as a single complication can be added to those with satisfactory results. The seriousness of unilateral vocal-cord paralysis is probably best evaluated in terms of the subsequent course. In 3 patients this occurred as a single complication, and because the later course was quite satisfactory, they can also be added to those with acceptable results. This number can also be supplemented by 2 patients who had temporary tetany. Thus, 113 patients, or 87 per cent, of the 130 followed for a minimum of six months are considered to have had a satisfactory outcome.

The 11 patients who suffered a recurrence or persistence of thyrotoxicosis, the 1 with permanent parathyropria, and 1 of those with vocal-cord paralysis should be regarded as having had unfavorable results. The case of vocal-cord paralysis is so classified because a unilateral injury occurred during the first stage of an intended two-stage procedure, and the patient refused further treatment because of this complication. In addition to these complications among the 149 patients subjected to operation, 4 deaths occurred. Thus, unsatisfactory results were obtained in 17, or 13 per cent, of the 130 cases that were adequately followed.

The data in the surgical treatment of Graves's disease (Table 1) indicate that 113 of the 130 pa-

tients followed are known to have had results that permitted a return to a normal life, and 13 had complications of some severity, mostly permanent in nature. Four patients did not survive the operation. Nineteen patients did not keep in touch with the hospital, so that a complete history of their cases is not a matter of record. It is also realized that a

THE RESULTS OF SURGICAL TREATMENT IN GRAVES'S DISEASE*

W P VANDER LAAN, M D,† AND ORVAR SWENSON, M D‡

BOSTON

THE introduction into this clinic by Astwood¹ of thiouracil and other potent antithyroid drugs for the medical treatment of Graves's disease resulted in a challenge to the concept that this condition is best treated surgically. Thus, there is a growing divergence of opinion concerning the relative merits of medical and surgical therapy in hyperthyroidism.

As a contribution to the discussion of this problem, a study has been made of the results of surgery for a period during which the performance of adequate subtotal thyroidectomy, combined with the proper use of iodine and other preoperative and postoperative measures, was the accepted method of therapy. This study is a review of all the cases of Graves's disease—that is, toxic diffuse goiter—surgically treated at the Peter Bent Brigham Hospital from 1933 through 1940. In the eight years reviewed, operations were performed in 149 cases in which a pathological report of diffuse hyperplasia of the thyroid gland was made. It is believed that such an analysis will establish a pattern against which similar controlled observations on patients treated with thiouracil may be compared.

It is the practice of the Surgical Service to follow these patients at regular intervals, and a majority of them were seen in the follow-up clinic of the hospital over a period of several years. For the purpose of this analysis, no result was considered satisfactory unless the patient had been under observation for at least six months after operation. When an unsatisfactory result was immediately apparent, however, this has been indicated, even though the patient's condition could not be checked through a minimum of six months. Nineteen patients whose condition at discharge was satisfactory failed to maintain contact with the clinic for a sufficient length of time to allow their final status to be evaluated.

Hypothyroidism after thyroidectomy was encountered in 18 cases. In 9 of these the classic signs of myxedema were found, the metabolic rate in 7 cases ranging from -31 to -47 per cent. The other 9 patients suffered from mild hypothyroidism. In all these cases the condition was well controlled with the administration of thyroid, and the patients eventually led useful and comfortable lives.

Vocal-cord paralysis was noted immediately following the surgical procedure in 7 cases, in 3 of which it was a single complication. In 1 case, which occurred after a first-stage hemithyroidectomy, the patient refused the second stage. Six patients had temporary unilateral paralysis on the basis of symptoms and postoperative examinations.

Four patients showed symptoms of hypoparathyroidism. In one there was evidence of permanent parathyropriav, on the basis of symptoms and of blood calcium and phosphorus levels. This patient was symptomatically controlled on vitamin D. The case was unusual in that preoperatively tetany could be induced by hyperventilation. One patient was followed for two months, at the end of which he had recovered from the tetany and did not return to the clinic, in addition to mild hypoparathyroidism, this patient sustained a vocal-cord paralysis and mild hypothyroidism. The third patient apparently suffered only a partial parathyroidectomy, since the symptoms of tetany disappeared five days after the operation. The fourth patient lost all signs of tetany within six months and continued in good health for at least eight years.

Persistent exophthalmos was observed in 13 cases. In only one of these did progression of the exophthalmos occur, and the patient was treated by the Naffziger procedure. One patient had marked unilateral, and one marked bilateral exophthalmos, in neither was it progressive. The remaining 11 patients had mild, persistent exophthalmos, without other postoperative difficulties.

Six patients experienced recurrence of thyrotoxicosis eight months to four years after operation. In 2 of these cases prolonged treatment with iodine induced permanent remission. Two patients underwent second operations, one experiencing a good result and the other disappearing from the clinic after the operation. There was no record of the courses in the remaining patients with recurrence after the diagnosis was established.

Five additional patients experienced persistence of the disease after operation. Two of these were referred to radiologists for radiation therapy. Two patients with persistent disease could not be followed. The fifth was of special interest in that three operations were performed. At the first, 76 gm of thyroid tissue was removed, a less extensive procedure than was considered optimal being carried out because of the poor state of the patient. Still was observed to have persistence of the disease but for seven years refused further treatment. The

INFANTILE CORTICAL HYPEROSTOSES*

Report of a Case

RICHARD K. WHIPPLE, M.D.†

PROVIDENCE, RHODE ISLAND

AFFEY and Silverman¹ in July, 1945, published the following description of a new syndrome entitled "infantile cortical hyperostoses"

The principal features of the disorder include onset in the early part of the first year, tender swellings in one or more of these sites — face and jaws, scapular regions and

Scurvy and syphilis were definitely ruled out. Infection, however, was not so satisfactorily excluded. Bacterial infection was not proved in any case. Virus infection or an allergic reaction was considered as a possible cause of the disorder.

Smith et al.² recently published an article relating to a condition occurring in infants and sometimes in older children characterized by irritability, fever, anemia with leukocytosis and a periosteal reaction of various bones. They reported 7 cases in which the most constant observation was a varying degree of periosteal reaction producing new bone and giving a laminated, onion-peel appearance. Biopsies of the affected bones and routine studies were of no aid in ascertaining the etiology of the condition. Biopsies of the affected muscles in 2

FIGURE 1 Photograph of Patient

Note the typical facies produced by bilateral swelling of the maxilla

extremities, and multiple scattered hyperostoses demonstrated roentgenographically in bones adjacent to the tender swellings and also in several other bones whose overlying soft tissues appear to be normal, clinically and roentgenographically. Biopsies of the affected bones in 3 cases showed only hyperplasia of the lamellar cortical bone.

Fever was noted to have occurred in 3 cases. In 1 case there was hyperirritability, and in 1 a blood count disclosed a moderately severe anemia. In all cases the swelling over the site of involvement tended to progress rapidly and to regress slowly.

cases, however, showed evidence of dystrophy suggesting a metabolic factor. Sulfadiazine and a high vitamin C intake did not affect the course of the disease. Penicillin was not tried. All the patients survived, most of the cases clearing completely.

The following case showed clinical manifestations and x-ray findings similar to those reported in the two papers cited above.

A. L., a 3-month-old boy, was admitted to the Charles V. Chapin Hospital on April 24, 1946, with a questionable diag-

few other recurrences of hyperthyroidism may have developed among the small number of patients whose records covered only six months of the post-operative period

Although this is a teaching hospital, thyroid surgery is not done by the house staff until late in the training period. In this connection, it may be noted that the incidence of complications in the hands of the house staff was not appreciably different from that of the visiting staff with one important exception. Three of the 4 deaths occurred after operations by members of the house staff, although this group performed less than half the procedures.

Since the end of the period during which this study was made, changes have taken place in the method of caring for patients with Graves's disease—chiefly in the preoperative use of thiouracil, alone or followed by iodine. This use of thiouracil may result in a lowered mortality because complete control of the metabolic evidences of the disease are made possible. It is apparent, however, that this will not appreciably alter such complications of surgery as hypothyroidism, parathyroprivia, vocal-cord paralysis or the persistence or recurrence of the disease. It may further be mentioned that the preoperative use of thiouracil entails the administration of this drug from three to eight weeks, and it is generally recognized that it is in the first nine weeks of treatment that the serious reactions to thiouracil are likeliest to occur.⁸ Thus, this form of treatment may subject the patients to most of the hazards of medical therapy and subsequently to those of surgery as well. It therefore seems probable that the results of surgery alone, as herewith recorded, approximate those to be expected with the preoperative use of thiouracil.

It is hoped that these figures will help to define the efficacy that medical treatment must achieve if it is to replace surgery in the therapy of Graves's

disease. That such a definition is necessary can readily be demonstrated. Although much has been written about the surgical treatment of this disorder, few authors have described the exact pre-operative status of their patients. Thus, Frazee and Mosser,⁹ describing the end results from the surgical treatment of hyperthyroidism, fail even to mention hypothyroidism, nerve injuries or parathyroprivia. Possibly, this lack of scrutiny was fostered by the absence at that time of a satisfactory alternate method of treatment.

SUMMARY

A review of the records of 149 patients surgically treated for Graves's disease at the Peter Bent Brigham Hospital from 1933 to 1940 showed that satisfactory results were obtained in 113 cases. Persistent or recurrent thyrotoxicosis, lasting parathyroprivic tetany or serious vocal-cord paralysis followed operation in 13 cases, and 4 patients died. The records in 19 cases were incomplete for a minimum of six months following operation.

erved to be rapidly enlarging. During that time the child took his food fairly well but vomited occasionally. Physical examination disclosed a well developed and well nourished but slightly pale infant. In the right parotid region there was a rather firm, nonred swelling that seemed to be attached to the ramus of the jaw (Fig. 1). Palpation of this area caused the child to cry. The mouth showed no signs of disease.

Examination of the blood revealed a red-cell count of 80,000, with a hemoglobin of 68 per cent, and a white-cell count of 24,000. Nineteen days later the white-cell count was 29,800, with 40 per cent neutrophils, 47 per cent lymphocytes, 9 per cent monocytes, 3 per cent eosinophils and 1 per cent basophils. Examination of the urine showed an occasional granular cast and an occasional white cell per high-

the calvarium external hyperostoses of both parietal bones can be demonstrated in the film of May 7, 1946. In a later film of the thorax, a massive cortical thickening of the right clavicle is seen. The remainder of the skeleton is normal roentgenographically. There are no signs of scurvy, syphilis or rickets.

The patient continued to run an intermittent fever, the temperature going as high as 102.5°F, and continued to be irritable. During his first stay in the hospital, he received a total of 2,400,000 units of penicillin intramuscularly and at another time received 10 gm of sulfadiazine. Neither of these agents altered the course of the disease.

The swelling in the right side of the face continued to enlarge, and about 2 weeks after admission a 4-cm, raised,

FIGURE 5 Lateral Projection of the Lower Left Ribs

in the sediment on several specimens. Nose and throat cultures were negative for diphtheria bacilli and hemolytic streptococci. The spinal-fluid findings were normal. A blood culture was sterile after 7 days' incubation. Tuberculin and blood Wassermann reactions were negative. The serum calcium was 9.7 mg, and the serum phosphorus 5.4 mg per 100 cc.

X-ray films of the jaws, skull and the entire skeleton were not revealing, and at that time the diagnosis was thought to be mainly confined to a lesion in the parotid gland. The second set of plates, taken about 3 weeks after admission, revealed definite changes in the mandible, the differential diagnosis varied between an infectious process, osteomyelitis and sarcoma.

The diagnosis of infantile cortical hyperostoses was then entertained, and the plates (those taken before May 26) and a copy of the clinical abstract were sent to Dr. John Caffey, who confirmed the diagnosis and interpreted the plates as follows:

Cortical hyperostoses are visualized in several sites of the skeleton. There is a massive mandibular hyperostosis confined to the right side of this bone, which thickens the body, ramus, coronoid process and articular process. In

red area that at first seemed soft appeared in the right occipitoparietal region. This mass was needled, and a culture of the solid material obtained grew out a few colonies of *Staphylococcus albus* and a rare one of *Staphylococcus aureus*. This was followed by the appearance of a similar mass on the left side of the head.

About 1 month after admission, following a transfusion, examination of the blood showed a red-cell count of 4,330,000 with a hemoglobin of 76 per cent and a white-cell count of 18,550. The differential was relatively unchanged. The white-cell count on June 20 was 36,450, with 34 per cent neutrophils, 63 per cent lymphocytes and 3 per cent monocytes.

On May 29, the patient was transferred to the Rhode Island Hospital for further treatment. On the morning of transfer a painful reddish swelling was noted in the region of the right sternoclavicular junction. The following is a detailed x-ray report from the Rhode Island Hospital on films taken on June 8.

Skull The calvarium is not enlarged. In the posterior parietal region and in the posterior portions of the occipital bone, there are several scattered patches of thickening of both the internal and external plates, together with small

nosis of parotitis. The weight at birth had been 8 pounds, 4 ounces, and the birth was stated to have been normal. A slight fever of unknown etiology during the first week of

MEDICAL PROGRESS

SYPHILIS

G MARSHALL CRAWFORD, M D *

BOSTON

WITH the termination of World War II and the return of several million young men to civilian life, the program for the control of syphilis faced with a great problem. In spite of the best wartime venereal-disease rates for any nation history, it is exceedingly important that consistent effort be maintained to eradicate syphilis. Even extremely efficient military supervision at separation centers cannot prevent the release of some cases of uncontrolled fresh infection. The cessation of large-scale effort by the armed forces requires increased public-health activity. Plans for the future in this respect, in addition to the continued study of newer methods of therapy, constitute the most significant phases of the problem of syphilis at present.

PUBLIC HEALTH

The most widespread case-finding program ever attempted was introduced by Selective Service before the United States entered the war. Protection of the armed forces from infection was greatly furthered by intensive contact-tracing measures instituted by the United States Public Health Service and local health departments. Most of the burden of this work now falls to civilian health authorities in the face of an increasing number of young men returning to civilian life. A great deal of careful planning for further procedures is required. Lacking the uniformity of military control, the Nation must return to the enforcement of laws and regulations by each community. It has been pointed out that a loose legal framework is now in use in many states for control of the venereal diseases.¹ Existing laws and regulations are for the most part merely adaptations of those designed for the control of other infectious diseases. Since each contagious disease presents unique problems, the application of such laws to any one type of infection cannot be expected to give the best possible results. As the laws stand, the principles of individual civil liberty are not always sufficiently protected. Health departments guarding the public against venereal disease ought not to depend wholly on law-enforcement machinery. Coercive methods should be used only as a last resort in the exceptional patient who is infectious and proves refractory to all methods

of persuasion. It may seem hopeless in some cases to obtain co-operation through persuasion and education, but experienced workers in this field find that it can be done in all except a few cases. When rapport can be established with such a recalcitrant patient, it is usually productive of far greater and more lasting co-operation. Resorting to enforcement of regulations by police officers often results in still greater antagonism.

Incidence of Syphilis

A survey of 5000 military inductees who were suspected of having syphilis showed that 570 (11.4 per cent) were proved to be completely free of the disease.² Most of these cases were included on the basis of a single positive blood test. There was considerable doubt concerning the diagnosis in an additional 6.3 per cent, and another 10.6 per cent were probably cured of the infection. Thus, only slightly more than 70 per cent of the original 5000 suspected cases were shown to have syphilis that required attention. Nearly 60 per cent of the patients in this group had not been treated and had had previously unrecognized infections. This emphasizes the great ease with which syphilis may spread unobserved through the general population and probably through the hands of many practicing physicians. In all, the blood serologic tests for syphilis of the Selective Service disclosed more than 700,000 cases.³

A study of venereal-disease rates in the Army after the termination of fighting in various theaters of operation revealed a sharp rise in the incidence of infections.⁴ These data included both the war areas and the United States itself. The relaxation of military discipline, compulsory educational procedures, provision of prophylaxis and treatment of infected military personnel, as well as the resultant loss of contact information, will sharply increase the burden on civilian health authorities. Although separation centers examined all soldiers for evidence of venereal disease within forty-eight hours of release and treated those with infection, many early cases doubtless slipped through during the stage when a diagnosis was impossible. The United States Public Health Service received reports on all infected soldiers requiring follow-up care and in turn notified the appropriate state health departments regarding the need for further diagnostic

*Instructor in dermatology, Harvard Medical School; assistant dermatologist, Massachusetts General Hospital.

areas of punctuate decalcification. One of these areas corresponds to the region of soft-tissue prominence in the right side. The soft-tissue prominence on the left side does not correspond to a similar area. No other definite productive or destructive bone lesion is seen elsewhere in the skull. There is no diastasis of the sutures.

Mandible. The entire mandible shows a diffuse general enlargement, with a somewhat lobulated inferior border (Figs 2 and 3). On both sides the limits of the original bony mandible can be distinguished, together with the additional layers of fairly solid bony substance. The outlines are smooth. No destructive areas are visible.

Clavicles. The left clavicle shows a large spindle-shaped mass of bony material surrounding somewhat more than the lateral half of the bone chiefly along the upper surface (Figs 3 and 4). The bony mass is uniform and also shows a slight lobulation in places. No destruction of the original clavicle can be seen. The right clavicle shows a more advanced stage of apparently the same process (Figs 3 and 4). Here, the additional bony accretion is also along the upper surface, where there is likewise a definite, lobulated peripheral outline.

Spine. The cervical, thoracic and lumbar spine shows a normal alignment and no definite productive or destructive bony lesion. There are no definite congenital anomalies.

Ribs. On the left side the 3rd, 4th and 5th ribs show zones of similar bony deposits along the axillary portions (Figs 4 and 5). The inner surfaces of these bones are projected in two areas along the lateral costal wall resembling lines of pleural exudate. Similar appearances are also seen along the anterior portions of the 9th, 10th and 11th ribs on both sides.

Pelvis. No definite bony abnormalities are observed in the pelvic bones. Both hip joints show normal development for the patient's age.

Long bones. The examination includes both humeri and the entire lower extremities on both sides. No definite productive or destructive bony lesion is noted in any of the bones.

Conclusions. The appearances are consistent with those found in a newly described syndrome, which has been called "infantile cortical hyperostoses."

On return to this hospital about 2 weeks later, the clavicles were both enlarged, they were not red but were slightly

tender to palpation. The two swellings on the head had decreased in size but were still firm and slightly red. The swelling on the right side of the head had broken down. The right jaw looked larger, and with a finger inside the baby's mouth and one outside, the bony reaction was palpable between the fingers. On June 22 the left jaw became involved in a process similar to that involving the right on admission. The left half of the mandible was larger than the right.

The clinical features, laboratory data and x-ray findings of this case conformed with the material gleaned from the cases presented by Caffey and Silverman¹ and Smyth et al.² The main features were hyperirritability, fever, leukocytosis and anemia. The x-ray films of the mandible, clavicles and certain ribs showed the typical reaction described by one author as a periosteal reaction² and by another author as hyperostosis of the cortices.¹

This case was unique in the fact that there was involvement of the skull and bones of the calvarium.¹

It is remarkable that these lesions develop so rapidly and regress so slowly, but if this patient follows the clinical course of those in previous cases of this kind, the prognosis is good.

SUMMARY

A case of infantile cortical hyperostoses is presented. Penicillin and sulfadiazine proved to be of no value in the treatment of the patient.

its who completed proper therapy by the older time methods

The control of commercialized prostitution was fixed somewhat after the termination of wartime measures¹² The United States Public Health Service and the American Social Hygiene Association are exerting every effort to continue this important phase of the control of syphilis Hawaii has had a particularly severe problem in this respect,¹³ and the control of prostitution instituted during World War II resulted not only in a drop in venereal-disease rates but also in fewer sex crimes¹⁴

Mortality Rates

A study of the compilation of data by the Bureau of the Census relating to mortality attributable to syphilis reveals interesting material¹⁵ Since 1939 there has been a steady and appreciable decline in deaths due to syphilis, every region of the country contributing to the lowered rates Even in the South, where the highest incidence occurs, there has been a distinct decrease in mortality The most marked decline in death rates for syphilis is for infants under one year of age The rate in the United States as a whole in 1943 was less than one third that in 1933 The mortality rates for paresis have remained practically stationary in recent years A study of mortality of untreated syphilis in the male Negro indicates that the untreated disease probably reduces the span of life by about 20 per cent.¹⁶ A group of 410 Negroes were followed over a period of twelve years to determine this fact A control series consisted of a comparable age group of 201 uninfected Negroes A large proportion of those who died during the time of observation were examined post mortem The effect of the treatment of acquired syphilis on life expectancy has been estimated by a study of admissions to the University of Virginia Hospital over a twenty-year period,¹⁷ including 2908 patients, among these patients 202 deaths were reported Mortality data for the general population from the Virginia State Department of Health supplied control figures Some patients were followed for as long as twenty years, and the average period of observation was four years All causes of death were included in computing life expectancy It was demonstrated that there were highly significant differences between the life expectancy of patients with syphilis and that of the general population, which in that area is unusually stable so that the fluctuation in statistics caused by transients was at a minimum The syphilitic population under investigation was a treated group, owing to an intensive control program carried out over a long period of years It was demonstrated that the life expectancy among the syphilitic group was reduced from 10 to 12 per cent below that of the general population Since the amount of treatment received by these patients is not specified, no estimate can be made of the amount necessary to

counteract the influence of syphilis on life expectancy A comparison of these figures with the 20 per cent decrease in life expectancy among untreated cases¹⁶ indicates that the antisyphilitic therapy prolongs life Treatment should thus be effective in reducing mortality specifically due to syphilis and in offsetting to some extent the effect of syphilis in reducing life expectancy

Schamberg,¹⁸ in a review of the literature bearing on the statistical prognosis of syphilis as based on governmental mortality reports, clinical studies, death and autopsy findings, and life insurance data during the twentieth century, points out that the available evidence indicates that syphilis adversely influences life expectancy only through the effects of its late manifestations in the central nervous and cardiovascular systems He believes that life-insurance companies may insure, at standard rates, the majority of syphilitic patients applying for insurance with no risk of increased death losses This is at variance with the preceding reports,¹⁵⁻¹⁷ but it serves to emphasize the value of treatment The late crippling effects of visceral syphilis can practically always be prevented by adequate therapy instituted before damage has occurred There is a tendency among many physicians to de-emphasize the benefit of treatment in late asymptomatic syphilis This may be justifiable only if adequate therapy has been given in the past and the patient is properly followed

SEROLOGIC PROBLEMS

The diagnosis of syphilis on the sole basis of serologic tests of the blood is fraught with many hazards It cannot be overemphasized that such a diagnosis in the absence of any other finding should be made with exceeding care A clinical evaluation of the results of serologic tests for syphilis in 8000 consecutive cases in a marine hospital¹⁹ is an example of the difficulties that may be encountered One or more tests performed on admission were positive in 226 cases (2.9 per cent) Among these it was eventually decided that 16.8 per cent of cases had false-positive reactions due to upper respiratory infections, virus pneumonia, malaria, smallpox vaccination, scarlet fever, leprosy, balanitis, diabetes, jaundice, infectious mononucleosis, bone tuberculosis and pulmonary tuberculosis There were only 2 cases in which the so-called "general biologic reaction" was considered to account for a false-positive test Few patients with what were considered to be false-negative reactions were subsequently found to be syphilitic The standard qualitative simplified Kolmer-Wassermann tests were employed throughout, each positive test being repeated at least once The Kahn test is reported to have given a higher incidence of false-positive reactions It was concluded that the use of only one standard test may miss as high as 16 per cent of cases It should be emphasized that doubtful serologic tests for syphilis

procedures or treatment. It was the opinion of military authorities that the educational program represented one of the most important features in the control of venereal disease.⁶ This fact should be recognized by all public-health authorities and carried over into civilian life.

The incidence of syphilis in the United States showed a decrease from 1944 to 1945. Syphilis reported for the first time for the calendar year 1944 in the United States numbered 398,907 cases.⁶ This figure dropped to 335,586 cases reported for the first time in 1945.⁷ This represents a reduction of almost 16 per cent but concerns only the cases of syphilis discovered during that period. The new infections (primary and secondary cases) were found to have occurred in almost identical numbers. This indicates that up to the end of 1945, the incidence of new cases of syphilis in the civilian population had not been influenced by the return of military personnel.

Control Measures

A second report on Alabama's legally required blood-testing program for syphilis on all persons between the ages of fourteen and fifty years is now available.⁸ The ninth county in which universal blood testing has been tried included the first predominantly urban group, this is the most populous county in the state and contains the largest city. The experience gained in mass blood testing in eight previous counties had established basic operating procedures and determined methods for ensuring public respect. The program was carried out by highly trained units designed to carry all publicity and establish primary blood-testing stations, auxiliary laboratories, records and statistics, record and reviewing personnel, physician and telephone follow-up service, personal interview and letter-writing follow-up service, secondary operational centers and a rapid-treatment center. This setup had been found to work with exceptional facility, and during a forty-two day period, 271,775 people were actually blood tested. On the first report, 41,072 persons were shown to have either a doubtful, positive or unsatisfactory serologic test for syphilis, only 32,655 had, by the time of publication, been proved to have syphilis. There were 765 patients with primary and secondary syphilis. This incidence of early syphilis was twelve times that normally reported to the health department during a comparable period. The number of infections brought under treatment could not have been accomplished in years of routine health-department work. Such a program of mass blood testing with follow-up study and immediate treatment, when properly publicized, could not but remove much early syphilis from any community. The cost is relatively low when the testing is done on such a large scale. The full value of these public-health measures is difficult to estimate. It should be pointed out that such a

gain against syphilis could be permanently held only if the program were continued at regular intervals. The repetition of such surveys for the group from fourteen to thirty-five years of age seems especially important. Alabama should receive great credit for the institution of such measures on a state wide basis, and this program may well serve as a model for future efforts by others. A similar campaign has been reported from San Antonio, Texas.⁹ Such measures should at least accomplish extensive health education, and even if that were the most noteworthy achievement, the effort would still be distinctly worth while. The importance of the preliminary publicity and education of the public that precede mass surveys cannot be overemphasized. In San Francisco a well conceived educational and case-finding program has been instituted in the industrial field.¹⁰ Educational efforts were directed toward labor groups, and after education of the union heads, the campaign went well. An appreciation of public-health services was fostered among industrial leaders, and with the confidence of both labor and management, the public-health service was able to function smoothly. This illustrates how special groups can be approached to create public awareness of the health, welfare and moral aspects of venereal-disease control.

The value of contact tracing with all new infections cannot be too heavily stressed. An excellent example of how much early syphilis can thus be tracked down may be seen in the story of a small outbreak of early syphilis in western New York.¹¹ Five patients with early cases divulged the names of 25 persons as contacts, and it was possible to locate 23 of these. Nineteen were found to be infected, and all cases but one were of recent origin. Eight of the infected contacts might have failed to see a physician except for the contact investigation. Prompt reporting by private physicians of all cases and intensive epidemiologic investigation can be expected to bring to treatment many patients with early infectious syphilis who would otherwise go untreated and continue to spread infection. Public health measures are vital, but there is no practicing physician anywhere who cannot contribute valuable assistance by personal effort in contact follow-up procedures.

Hospitals are an aid in case-finding when routine serologic tests for syphilis are performed on every admission. Many thousands of new cases have been discovered by this means, and the procedure should be strongly urged in all hospitals in which such tests are not at present done. Hospitals will play an increasingly important role in the control of syphilis owing to the advent of penicillin. Nearly 100 per cent of all patients with syphilis could complete the required amount of treatment in a short period if institutionalized. This is too great a burden for present hospital facilities but is a worthy goal, in view of the comparatively small percentage of pa-

laboratory studies, it was necessary in most cases to establish the diagnosis on the basis of biologic findings. Elaborate batteries of tests evaluated according to a special classification procedure proved to be the most satisfactory method of studying the material. Many borderline cases are extremely difficult to decide. One might question the possibility that it could become too costly to give treatment in doubtful cases when penicillin therapy is developed to the point of ready facility of application. Another report covers the observation of 300 healthy seronegative reformatory inmates who gave blood donations.²⁶ Almost 100 per cent of these donors developed some degree of positivity, which reverted to negativity in eight weeks. The serums of these patients were subjected to repeated tests for syphilis by six serodiagnostic clinics. A second report from multiple donors observed at the American Red Cross Blood Donor Service²⁷ indicated that there is a tendency for positive serologic reactions to diminish rather than to increase with multiple donations.

Seroresistance

An unusual article by Moore,²⁸ which is worth reading by anyone who treats syphilis, presents a discussion of the problem of seroresistance (so-called "Wassermann fastness") in syphilis, primarily to guide the physician in discussing this matter with his patient. The difficulties encountered in attempting to explain such situations to even the most intelligent person are graphically portrayed, and simple explanatory devices outlined. The reasons for giving treatment even when no physical evidence of syphilis exists and no history of the disease is obtained are shown. The value of yearly physical examinations and semiannual tests of the blood are pointed out. This paper answers many questions that frequently confront both the physician in general practice and the specialist dealing with syphilis.

CLINICAL PROBLEMS

With the bulk of emphasis in current literature dwelling on various phases of penicillin therapy and public-health problems, there have been fewer reports than usual on the everyday clinical problems in the management of syphilis. A few articles nevertheless merit consideration.

Beerman²⁹ has presented an instructive survey of reinoculation of human beings with *Treponema pallidum*. He points out that the introduction of each new curative agent or method of therapy is accompanied by increased reports of reinfection. Beerman believes that part of this may be a reluctance on the part of the supporters of a new therapy to accept the possibility of relapse. After a complete and extensive review of the literature, it is pointed out that reinoculation with *T. pallidum* can be successful in all phases of untreated human syphilis

(superinfection). The reinoculation lesions resemble those representing the phase of the patient's syphilis at the time of reinoculation. Beerman believes that reinoculation of patients supposedly "cured" of syphilis (reinfection) rarely occurs. He does not consider the data on reinoculation of human beings with syphilis sufficient to answer definitely the question whether reinfection is possible in man. Although there may be some justification in the claim that foreshortened treatment schedules prevent the development of immunity, the data available cannot be construed as a rational basis for the voluminous number of cases of reinfection reported in patients treated by intensive therapy. It must be remembered, however, that there are no absolute criteria of biologic cure or adequate means of identifying asymptomatic infections in man, and it is possible that reinfections may take place on a scale larger than hitherto suspected. In this connection, it is interesting to note the report of a chancre developing in a patient with cardiovascular syphilis.⁴⁰ The patient had had adequate therapy for syphilis, and the serologic tests had been negative for several years. The syphilitic cardiovascular disease had apparently been arrested. Such a case presents a nice problem of reinfection versus superinfection.

The occurrence and significance of fever in syphilis have received little attention, since succeeding generations appear to offer milder clinical manifestations of the disease. Wallman⁴¹ has reviewed the significance of fever in syphilis. He points out that it may occur in the secondary phase of the disease and is occasionally observed in early syphilis without eruption, an intermittent fever can occur and may be confused with malaria. A moderate temperature accompanied by generalized muscle pain and gastric disturbance is occasionally found. There are also completely irregular patterns. Hypopyrexia may also occur in either acquired or congenital syphilis. Pyrexial activations during therapy are discussed. Thermal reactions may also be seen when latent syphilis becomes activated, whether spontaneously or by physical trauma, intercurrent disease and so forth. Wallman regards thermal reactions occurring during the treatment of syphilis as an index to the resistance of the *T. pallidum* and believes that in such cases the dosage of drugs should be increased or other measures employed.

Jordon and Dolce⁴² have recently recorded observations in 169 cases of late syphilis over a period of ten years or more. It was found that there is a decided tendency for the blood serum of the patients who were untreated or poorly treated to fluctuate over a period of years. Consequently, the negative serologic reaction in such cases, even on repeated examination, does not necessarily mean spontaneous serologic cure. Approximately 25 per cent of the untreated or poorly treated patients with latent syphilis became seronegative spontaneously and remained so over a period of years. From 20 to

should not be regarded as insignificant any more than they can be used as direct evidence of syphilis. Nor can a negative report be overlooked in the face of clinical evidence. The value of more than one test for syphilis, as well as the employment of different types of reactions, is further emphasized by the fact that some procedures give lower percentages of false-positive reactions under different circumstances.²⁰ The Hinton test, for example, shows a lower incidence of such reactions in malaria. Upper respiratory infections and immunization procedures produce fewer false-positive reactions with the Kolmer type of complement-fixation test. Temporary variations in the seroglobulins may give rise to temporary false-positive tests for syphilis. In the vast majority of cases, false-positive reactions are of low titer and usually disappear within a comparatively short time. The possibility of technical errors must always be kept in mind. The diagnosis of syphilis on the basis of blood serologic tests alone may be so complicated as to require repetition of the tests for weeks or months, as indicated in each case. A rather complete summary of this problem, presented in readable form by Kampmeier,²¹ merits the consideration of anyone faced with such a diagnostic dilemma.

There are continued attempts to refine the techniques and to develop new methods designed to eliminate nonspecificity in the blood serologic tests for syphilis. Kahn²² reports on the use of the so-called "zone reactions" — a serologic method based on the use of multiple serum-antigen ratios that is mainly useful in known or suspected cases of syphilis in which serodiagnostic tests give what are suspected of being false-negative results. Kahn also believes that the procedure provides a better criterion of cure than negative results by standard tests. Rein and Elsberg²³ have published a critical dissertation on the practical value of current verification tests in the serodiagnosis of syphilis. Six methods were considered that have been described for the differentiation of the true-positive from the false-positive serologic reactions for syphilis. It is the opinion of these authors that none of the verification procedures have been able to distinguish consistently between true-positive and false-positive tests. This belief, shared by a number of other serologists, in addition to the impracticability of verification tests in most laboratories, has limited the use of such procedures to large institutions where research facilities are available. Microflocculation tests for syphilis using cardiolipin antigens have recently been described.^{24, 25} It is claimed that a comparison of the test results by these techniques with those by other methods indicates a satisfactory level of sensitivity and specificity. There is some belief that cardiolipin antigens may prove more sensitive than those previously employed. Quantitative serologic tests continue to be used for special diagnostic problems.²⁶ These are also impractical for routine

application because of the larger amount of serum required and the higher degree of technical skill involved. It is possible to follow the serologic trend in various phases of syphilis under treatment with such quantitative tests, which are of great value in estimating the effectiveness of treatment in early syphilis. The application of these principles to various phases of syphilis has recently been discussed.²⁷

False-Positive Reactions

A careful survey was undertaken by the syphilis division of the Johns Hopkins Hospital²⁸ to determine whether positive blood serologic tests for syphilis may be differentiated from reactions due to other factors by means of serologic methods at present available. Serums were obtained from known cases of syphilis, from patients having biologic false-positive tests, from cases of undetermined status, from a normal group and from cows and horses. Specimens were shipped to various laboratories for the performance of numerous serologic tests, including several special techniques. According to this study, there is no "serologic pattern" that will differentiate true from false reactions or one type of syphilitic infection from another. Apparently, no single test or combination of tests was found capable of diagnosing true from false positivity by examination of a single specimen of serum. Until new serologic methods can be developed, differential diagnosis between syphilis and other reagin-producing diseases must continue to be made by clinical examination and by serial quantitative serologic tests repeated over periods of days to years. The frequent warning regarding clinical study of each case²⁹ and attempts to rule out causes for false-positive reactions³⁰ are to be found in practically every article dealing with this problem. Varicella is one of the more recently described possible causes of false-positive serologic tests for syphilis.³¹ Lymphogranuloma venereum has likewise been added to the list.³² The influence of malaria on the serologic tests for syphilis continues to be studied.³³ Apparently, there is no relation between the degree of temperature in malaria patients and the number of false-positive reactions. There is also no apparent correlation between the number of attacks of malaria and the development of positive serologic reactions for syphilis, nor has this disease been proved to produce any change in the spinal fluid.³⁴

The occurrence of false-positive reactions in serologic tests for syphilis following repeated blood donations has received considerable study. Stokes et al.³⁵ reviewed the findings among specimens collected from 210,261 Red Cross blood donors over a nine-month period, 489 of which gave definite positive reactions to serologic tests for syphilis. Of these, 79 subjects were selected for intensive follow-up and evaluation, 40.5 per cent were finally adjudged to have syphilis. After exhaustive clinical

it seems advisable to withhold antisyphilitic therapy until a definite diagnosis can be established

THERAPY

The use of penicillin in the treatment of syphilis is again considered a separate main division in this progress report

Intensive Therapy

Shaffer⁴⁸ has reviewed two groups of patients with early syphilis treated by separate intensive therapy schedules, 210 patients received a fifteen and two-week schedule consisting of thirty injections of Mapharsen and eight injections of bismuth. Reactions necessitated the discontinuance of treatment in 7 cases. A second group of 352 patients was placed on an eight-week schedule that included twenty-four injections of Mapharsen and eight injections of bismuth given concurrently. Discontinuance of treatment was necessary in 8 cases. There were no fatal reactions in either group. Shaffer found that the results of treatment were essentially satisfactory in both series, but only among those who followed treatment faithfully. His opinion is that these intensive plans are satisfactory and adaptable to either private practice or clinics, but that case holding presents the greatest problem. A less satisfactory rate of cure was observed in a group of 206 patients with early syphilis, given two injections of Mapharsen daily for a period of six days by other workers.⁴⁹

Several studies of liver function in early syphilis under intensive arsenotherapy have been reported. In one group the tests employed were the blood prothrombin concentration, the serum bilirubin level, the retention of bromsulfalein and the rate of hippuric acid synthesis.⁵⁰ Among the 22 patients only 3 were found to have normal liver-function tests prior to treatment, suggesting some degree of syphilitic hepatitis. All cases showed impairment of liver function by one or more tests subsequent to the administration of massive doses of arsenical drugs by the five-day intravenous method. The liver function of all patients returned to normal within six months after the arsenotherapy. This indicates that, although hepatic damage results from arsenotherapy, the injury is not permanent nor is it often sufficient to cause clinically recognizable liver disease. Another series of 49 patients receiving five-day therapy were studied with the following liver-function tests: plasma protein, cephalin flocculation, intravenous hippuric acid and sulfobromophthalein.⁵¹ Approximately 35 per cent showed evidence of liver damage prior to treatment, again indicating active hepatitis during the primary and secondary stages of syphilis. There was no evidence of liver damage in any of these cases subsequent to massive arsenotherapy. Approximately 90 per cent of patients with abnormal tests before treatment exhibited the same or improved liver-function tests

following arsenotherapy. These findings suggest that large doses of arsenoxide given within a five-day period do not usually produce detectable liver damage. The disagreement in these two reports^{50, 51} may be partially due to the diversity in liver-function tests employed.

The massive five-day to eight-day intravenous drip arsenotherapy of syphilis appears to be sliding further into disfavor. This method was studied over a period of ten years by numerous groups of investigators but never reached universal application because of the technical difficulties involved and the high incidence of serious and fatal reactions. Multiple-syringe programs for varying periods of days and weeks were in the process of being evaluated at the time of the advent of penicillin. Although these schedules showed great promise and fewer untoward effects, penicillin now bids fair to supplant them all. Combinations of penicillin and chemotherapy, as pointed out below, seem to show the greatest promise.

The use of hyperpyrexia in ocular conditions due to syphilis has recently received attention. One group of 35 cases was treated with specific antisyphilitic chemotherapy in conjunction with the use of the Kettering hypertherm.⁵² Four of 19 cases of syphilitic atrophy of the optic nerve showed improvement, clinical progression of symptoms was arrested in 7, and the remainder continued to progress. Four of 6 cases of acute syphilitic choroiditis were decidedly improved by this treatment. In 6 cases of acute iritis associated with secondary syphilis excellent therapeutic results were obtained. The therapy was also beneficial in the treatment of interstitial keratitis, with marked alleviation of severe pain and photophobia. A report by Bruetsch⁵³ from the Johns Hopkins Hospital concerns 250 patients with syphilitic primary optic atrophy treated with malaria. It is pointed out that the pathological basis of syphilitic optic atrophy is more like the process of dementia paralytica than that of tabes. Malaria therapy inhibits the inflammatory element, and the degeneration of the nerve fibers ceases. Since the inflammatory process usually advances from the periphery toward the interior, enough normal tissue of the central portions of the nerve is left for useful vision. For three years following malaria therapy the slow progression of failure of vision may continue. In patients who react favorably to this treatment, however, the constriction of the visual fields will gradually expand, evidencing capacity for recovery of partially damaged nerve fibers.

It has been found that there is some value in the use of electric shock in the treatment of dementia paralytica.⁵⁴ This should not be considered a treatment of choice, but regarded as an adjuvant method in cases in which hyperpyrexia, penicillin, chemotherapy and combinations of these may fail.

There has been a belief in some quarters that the

25 per cent of these patients (massed racial groups, including Negroes) developed some cardiovascular complication when observations were included over a period in excess of thirteen years. It was apparent that a blood serum that tended to fluctuate in degree of positivity indicated a relatively good clinical outcome, whereas the persistence of strongly positive reactions predicted a poor clinical outcome. As a corollary it was found that in patients with adequately treated latent syphilis there was a decided tendency for the blood serums to fluctuate. Frank, early syphilis did not appear to provide immunity to late complications. Adequate antisyphilitic treatment apparently reduces the hazard of late serious complications to a minimum, even though in patients with latent syphilis there was only a 17 per cent increase in long-term serologic reversals, compared to the 25 per cent spontaneous reversals after little or no treatment. In well treated latent syphilis there was no apparent relation between the state of the blood serum and the development of late complications. Arsenical drugs seemed more efficacious than heavy metals in preventing late complications. Twenty to twenty-nine injections of an arsenical drug were regarded as constituting adequate therapy. This should be combined with alternating courses of a heavy metal. More than this amount did not result in a reduction of complications. Forty to sixty injections, or possibly less, of a heavy metal appeared sufficient when combined with the adequate arsenical therapy. Further administration of heavy metal did not reduce the likelihood of late complications. The findings of these observers warrant more than the usual consideration. It has repeatedly been emphasized that prolonged periods of observation are essential to determine the adequacy of any form of therapy for syphilis or to gather adequate data of almost any sort concerning the disease. This is the first series on record of more than 40 patients followed for ten years or more in whom adequate examinations and repeated serologic tests were done. Such work requires time and is painstaking and tedious, but affords invaluable information.

The early diagnosis of cardiovascular syphilis has been stressed by Dressler.⁴⁵ A study of 1270 cases of proved syphilis resulted in a diagnosis of cardiovascular syphilis in 30.7 per cent. Seventy-eight of these cardiovascular cases were uncomplicated aortitis. These are comparatively high percentages. Of 128 patients with cardiovascular syphilis who recalled the chancre, a diagnosis of uncomplicated aortitis was made in 38 cases within ten years after the acquisition of infection. Dressler, reviewing his methods of study and criteria for the diagnosis of aortitis, believes that careful study enables one to establish the diagnosis earlier than is usually believed, and states that uncomplicated aortitis can be diagnosed clinically in a patient with an aorta of normal size. It has been claimed that

calcification in the ascending aorta is strongly indicative of syphilis.⁴⁶ A comparison of the clinical, roentgenologic and pathological findings in 44 autopsied cases of syphilitic aortitis were compared with those in a group of 62 autopsied cases of severe arteriosclerosis of the aorta. Linear calcifications in the ascending portion of the aorta were present on the roentgenograms in 22.7 per cent of the cases of syphilitic aortitis, whereas only 3.2 per cent of the arteriosclerotic group were found to have calcium deposits visible in the ascending aorta. Calcification in this location was considered to surpass the reliability of negative serologic evidence of syphilis. Such calcification was seldom found as an early sign of syphilitic aortitis, occurring most frequently in the older patients with relatively quiescent cases of syphilis. A description has appeared of 5 patients who developed serious syphilitic lesions of the vascular or cardiovascular organs in early adult life.⁴⁷ Clinical manifestations of syphilitic heart disease appearing in early decades are comparatively rare. The patients in this group varied from five to thirty-one years of age. The duration of infection in 3 of the cases was known to be two, thirteen and fifteen years. Post-mortem examinations were done in 4 cases.

Headaches after lumbar puncture have been studied in a statistical report by Underwood.⁴⁸ Incapacitating attacks occurred in 19 per cent of 500 cases in which punctures were done. Evidence was presented that bed rest following a lumbar puncture does not reduce the incidence of post-puncture reactions. If a severe headache results, however, bed rest for twenty-four to forty-eight hours should be advised. The use of caffeine with sodium benzoate intravenously may be of value in alleviating the discomfort of post-puncture headache if the patient cannot rest. Sedation before the puncture was not found beneficial. Patients presenting emotional reactions to the spinal tap had incapacitating reactions more frequently than calm, quiet persons. As has frequently been observed by others, patients with neurosyphilis had fewer post-puncture attacks than any other group. The problems encountered in the diagnosis of acute syphilitic meningitis were pointed out in a report of 9 cases, 5 of which presented diagnostic difficulties.⁴⁹ In 2 cases the symptoms developed while the patient was receiving treatment with bismuth preparations. Since syphilitic meningitis often improves without treatment and since patients with other types of lymphocytic meningitis may get well coincidentally with antisyphilitic treatment, such therapy cannot be considered a diagnostic test. Other difficulties that may be encountered are the occurrence of false-positive Wassermann reactions in the spinal fluids of patients with nonsyphilitic meningitis and occasionally false-negative reactions in patients with syphilitic meningitis. Unless the patient is critically

CASE 33071

PRESENTATION OF CASE

A twenty-seven-year-old engineer entered the hospital because of polydipsia and polyuria. Six and a half years before entry the patient had had an episode of pain in the right lower quadrant for which an appendectomy was performed. At that time the mesenteric lymph nodes were found to be enlarged. Two months later he was seen by a physician because of anorexia, fatigue, moderate exertional dyspnea and a weight loss from 158 to 146 pounds. He was referred to this hospital for further study.

Examination in the Out Patient Department showed palpable cervical, axillary and inguinal lymph nodes, but none were considered suitable for biopsy. An x-ray film of the chest revealed a sharply outlined lobulated mass, 9.5 cm. at its widest point, occupying the region of the great vessels opposite the pulmonary conus and obscuring the outline of the aorta. The lymph nodes at the lung roots were slightly enlarged. The trachea was not deformed or displaced. The lung fields were clear. On the basis of these findings, the patient was given 600 r of x-ray therapy to the mediastinum and 500 r to the groin and lumbosacral spine. Following this treatment there was marked clinical improvement. Several months later he began to have pain in the low back and left posterior hip, which disappeared after x-ray therapy (600 r). An x-ray film had shown an area of destruction in the sacrum. Several months later, while the patient was in another city, a biopsy of a cervical lymph node was reported as showing Hodgkin's disease. During the following two years enlarged lymph nodes appeared from time to time in the neck, mediastinum, axilla and groin. These were treated as they appeared by radiation, with rapid subsidence.

Four years before entry the patient complained of generalized itching, particularly on the legs. At that time there were lymph nodes, 1 or 2 cm. in diameter, in the neck and inguinal regions. The spleen extended to the costal margin on inspiration. X-ray examination of the chest was negative, there were no enlarged mediastinal shadows. He was given generalized as well as local radiation, and

received 15 cc. of radioactive phosphorus (equivalent to 0.44 mc.) intravenously. The itching of the skin was benefited by a constant intake of 50 cc. of viosterol (500,000 units of vitamin D) a week. This dosage of viosterol was continued until entry. Two months later the patient complained of pain in the low mid-back and down the thighs. X-ray examination of the lower spine showed areas of increased density in the tenth and twelfth dorsal and the first, second and third lumbar vertebrae. There was also a small soft-tissue mass in the paravertebral space on the left of the tenth dorsal vertebra, and some involvement of the medial portion of the right ilium. Radiation gave symptomatic relief, but the x-ray findings remained unchanged. Three years before entry the appearance of scattered warts on the legs was noticed. Six months later the only complaint was precordial pain occurring after severe exertion. There were fine inspiratory rales at the left apex posteriorly, and a chest film revealed a small, semicircular, soft-tissue mass between the left eighth and ninth ribs near the vertebra. Otherwise, the lungs were clear. After local radiation the symptoms disappeared, and the patient felt well, the weight reaching 174 pounds. A year before admission he had an attack of herpes zoster over the right side of the neck, upper chest and upper shoulder.

Four weeks before entry, the patient began to feel weak, tired and feverish. He lost his appetite and developed an annoying dryness of the mouth and an increasing thirst. He drank about 4 liters of water a day and passed large amounts of light-colored urine, voiding five or six times during the night. Occasionally, he felt an urge to urinate even though the bladder was not distended. He also became constipated, having only one bowel movement in three to five days, despite the taking of cascara and mineral oil. The eyes became sensitive to light and burned, particularly when he was doing close work. On waking in the morning he had some retching, but there had been no actual vomiting. For several days before entry the patient was forced to go to bed because of increasing malaise, weakness and drowsiness. He had vague muscle aches in the legs and diffuse headaches occurring about once a day, increased by motion of the head. The day before entry he had stiffness and aching in the lumbosacral region. While driving to the hospital, the patient found himself "weaving" all over the street and was unable to judge distances, so that several times he collided with the car ahead of him.

Physical examination showed a well nourished patient who appeared both acutely and chronically ill. He was drowsy and dozed off quietly after the examination. The respirations were deeper than normal. There were bilateral, soft, nontender cervical lymph nodes measuring about 1.5 cm. in diameter. The axillary and epitrochlear nodes were not

use of inoculation malaria for the treatment of neurosyphilis presented a hazard to other institutionalized patients. A recent survey of this problem indicates that accidental transmission of therapeutic malaria practically never occurs.⁵⁵

CASE 33071

PRESENTATION OF CASE

A twenty-seven-year-old engineer entered the hospital because of polydipsia and polyuria. Six and a half years before entry the patient had had an episode of pain in the right lower quadrant for which an appendectomy was performed. At that time the mesenteric lymph nodes were found to be enlarged. Two months later he was seen by a physician because of anorexia, fatigue, moderate exertional dyspnea and a weight loss from 158 to 146 pounds. He was referred to this hospital for further study.

Examination in the Out Patient Department showed palpable cervical, axillary and inguinal lymph nodes, but none were considered suitable for biopsy. An x-ray film of the chest revealed a sharply outlined lobulated mass, 9.5 cm. at its widest point, occupying the region of the great vessels opposite the pulmonary conus and obscuring the outline of the aorta. The lymph nodes at the lung roots were slightly enlarged. The trachea was not deformed or displaced. The lung fields were clear. On the basis of these findings, the patient was given 600 r of x-ray therapy to the mediastinum and 500 r to the groin and lumbosacral spine. Following this treatment there was marked clinical improvement. Several months later he began to have pain in the low back and left posterior hip, which disappeared after x-ray therapy (600 r). An x-ray film had shown an area of destruction in the sacrum. Several months later, while the patient was in another city, a biopsy of a cervical lymph node was reported as showing Hodgkin's disease. During the following two years enlarged lymph nodes appeared from time to time in the neck, mediastinum, axilla and groin. These were treated as they appeared by radiation, with rapid subsidence.

Four years before entry the patient complained of generalized itching, particularly on the legs. At that time there were lymph nodes, 1 or 2 cm. in diameter, in the neck and inguinal regions. The spleen extended to the costal margin on inspiration. X-ray examination of the chest was negative; there were no enlarged mediastinal shadows. He was given generalized as well as local radiation, and

received 15 cc. of radioactive phosphorus (equivalent to 0.44 mc.) intravenously. The itching of the skin was benefited by a constant intake of 50 cc. of viosterol (500,000 units of vitamin D) a week. This dosage of viosterol was continued until entry. Two months later the patient complained of pain in the low mid-back and down the thighs. X-ray examination of the lower spine showed areas of increased density in the tenth and twelfth dorsal and the first, second and third lumbar vertebrae. There was also a small soft-tissue mass in the paravertebral space on the left of the tenth dorsal vertebra, and some involvement of the medial portion of the right ilium. Radiation gave symptomatic relief, but the x-ray findings remained unchanged. Three years before entry the appearance of scattered warts on the legs was noticed. Six months later the only complaint was precordial pain occurring after severe exertion. There were fine inspiratory rales at the left apex posteriorly, and a chest film revealed a small, semicircular, soft-tissue mass between the left eighth and ninth ribs near the vertebra. Otherwise, the lungs were clear. After local radiation the symptoms disappeared, and the patient felt well, the weight reaching 174 pounds. A year before admission he had an attack of herpes zoster over the right side of the neck, upper chest and upper shoulder.

Four weeks before entry, the patient began to feel weak, tired and feverish. He lost his appetite and developed an annoying dryness of the mouth and an increasing thirst. He drank about 4 liters of water a day and passed large amounts of light-colored urine, voiding five or six times during the night. Occasionally, he felt an urge to urinate even though the bladder was not distended. He also became constipated, having only one bowel movement in three to five days, despite the taking of cascara and mineral oil. The eyes became sensitive to light and burned, particularly when he was doing close work. On waking in the morning he had some retching, but there had been no actual vomiting. For several days before entry the patient was forced to go to bed because of increasing malaise, weakness and drowsiness. He had vague muscle aches in the legs and diffuse headaches occurring about once a day, increased by motion of the head. The day before entry he had stiffness and aching in the lumbosacral region. While driving to the hospital, the patient found himself "weaving" all over the street and was unable to judge distances, so that several times he collided with the car ahead of him.

Physical examination showed a well nourished patient who appeared both acutely and chronically ill. He was drowsy and dozed off quietly after the examination. The respirations were deeper than normal. There were bilateral, soft, nontender cervical lymph nodes measuring about 1.5 cm. in diameter. The axillary and epitrochlear nodes were not

palpable. In the left groin there was a 5-cm., soft, elongated, nontender mass. The heart and lungs were normal. The liver edge was percussed 2 to 3 cm. below the costal margin. There was a hydrocele 9 cm. in diameter on the left side. The extremities were normal except for scattered large warts over the legs. Examination of the cranial nerves was negative. The pupils were normal and reacted well to light and accommodation. The neck was stiff, and the Kernig test was positive bilaterally. The finger-to-nose test was negative. There was no adiadokokinesis, and no muscle weakness. The tendon reflexes were normal. The abdominal reflexes were absent. The plantar response was flexor bilaterally, sensation was normal.

The temperature was 101°F., the pulse 104, and the respirations 24. The blood pressure was 130 systolic, 85 diastolic.

Examination of the blood disclosed a red-cell count of 2,940,000, with a hemoglobin of 10.5 gm., and a white-cell count of 4500, with 86 per cent neutrophils. The total protein was 5.6 gm. per 100 cc., with an albumin-globulin ratio of 1.5. The nonprotein nitrogen was 52 mg., the calcium 12.6 mg., the phosphorus 4.3 mg., the alkaline phosphatase 1.9 mg. and the fasting blood sugar 145 mg. per 100 cc., and the carbon dioxide 30.5 milliequiv. per liter. The prothrombin time was 22 seconds (normal, 14 seconds). The van den Bergh reaction and a cephalin-flocculation test were negative.

The urine was slightly cloudy and straw colored. The specific gravity was 1.005. The sediment contained 8 to 12 white cells and a few granular casts per high-power field. No sugar or albumin was found. A urine culture yielded abundant colonies of *Staphylococcus albus* and alpha-hemolytic streptococcus. The phenolsulfonephthalein test showed 45 per cent excretion in two hours. The urinary calcium excretion was 1290 mg. in twenty-four hours. A stool was brown, liquid and guaiac negative.

A lumbar puncture revealed an initial pressure equivalent to 150 mm. of water, with normal dynamics. The fluid was clear and colorless and did not clot on standing. There were 450 cells per cubic millimeter, of which 80 to 90 per cent were lymphocytes and the remainder polymorphonuclears. The total protein was 58 mg., the sugar 70 mg. and the chloride 111 mg. per 100 cc. The gold-sol curve was 0001122100. Smears of the spinal-fluid and urinary sediment were negative for acid-fast organisms.

During a twenty-four-hour period following the intramuscular ingestion of 1 cc. of pitressin tannate, the fluid intake fell from 4500 cc. to 2750 cc., and the urinary output went from 3500 to 2000 cc.

An x-ray film of the chest showed a milary nodular process throughout both lungs. There was also an area of calcification in the anterior aspect of the right side of the chest close to the sternum. A

skull film showed multiple areas of calcification in the left frontal region.

On the seventh hospital day the patient became disoriented and increasingly drowsy. He developed a coarse tremor of the fingers on extension. A second lumbar puncture revealed an initial pressure equivalent to 240 mm. of water. The fluid had a ground-glass appearance and formed a pellicle on standing. A smear showed one definite acid-fast organism, a subsequent smear on another specimen was negative. The spinal-fluid culture was negative. Slit-lamp examination showed a keratitis similar to that seen in hypercalcemia.

During the fourth week in the hospital the patient began to lose ground rapidly. He had nausea, vomiting and persistent hiccough. On the thirty-third hospital day he became comatose. He developed a right facial palsy, and the left pupil became dilated. The temperature rose to 104.5°F., and the respiratory rate to 45. The patient died on the thirty-fourth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. RICHARD J. CLARK: This patient's illness may be considered to have started with the right lower quadrant pain for which an appendectomy was performed and following which definite signs of debility appeared. We are told in the early portion of the protocol that a biopsy showed Hodgkin's disease. Certainly, all the preliminary evidence of lymph-node enlargement, including para-aortic and mesenteric nodes, evidence of bone involvement, response to radiation and appearance of pruritus are consistent with this reported diagnosis. I shall accept this as a basic working diagnosis in spite of the danger of so doing in these exercises.

We note that the patient was placed on a large dose of vitamin D, — 500,000 units a week, — which he continued over a period of four years. This is a matter to be kept in mind for future consideration. Precordial pain is mentioned only once, and there were no other findings referable to the heart, therefore, I shall dismiss this as evidence of recurring chest tumor. The development of herpes zoster is a frequent occurrence in Hodgkin's disease.

Four weeks prior to entry we are first told of feverishness, which is perhaps surprising. In long-standing Hodgkin's disease the presence of fever would have been expected earlier. This raises the possibility of some complicating infection. Evidence of polyuria then appeared, and I shall discuss this in further detail subsequently. The urgency of urination and increasing constipation raise the possibility of a pelvic mass. Shortly before entry evidence of central-nervous-system involvement — consisting of headache, photophobia, stiffness of the back and unsteadiness — first appeared, and on arrival at the hospital we find objective confirmation in the patient's drowsy and dazed condition.

ologic examination revealed evidence of meningeal involvement without positive evidence of any in the brain proper

Laboratory studies indicated a blood picture compatible with chronic Hodgkin's disease. There was an elevation of the nonprotein nitrogen, an elevated calcium and a normal phosphorus with a low phosphatase. The blood sugar was elevated on the determination given, and yet we are not told of any glycosuria, this raises the bare possibility of involvement of the pancreas by Hodgkin's disease. The urinary calcium increase, as I understand it, is tremendous. The normal value is 150 to 200 in twenty-four hours. There was evidently urinary-tract infection and possibly a decreased renal function, although we could tell more about that if we knew what the fractional phenolsulfonephthalein excretion showed. There was a low urinary specific gravity, but with the polyuria this is not surprising. One may judge from the total picture that there was probably some decrease in the renal function. The spinal fluid showed an increase to 450 cells per cubic millimeter, chiefly lymphocytes, an increase in protein, a normal sugar and only a slightly lowered chloride. These findings certainly give evidence of some type of meningeal involvement. The sugar content was too normal for a bacterial infection. Could this have been a tuberculous meningitis? We know that active tuberculosis does occur in association with Hodgkin's disease. On the other hand, the spinal-fluid findings are against tuberculosis in that the sugar was rather higher than one would expect to see in this condition, and the chloride was not so low as one would anticipate. For these reasons, it is my inclination to say that Hodgkin's involvement of the meninges is likely. We know that this does occur, and I am told that this spinal-fluid picture is compatible with a lymphomatous involvement of the meninges.

The x-ray report of a nodular process throughout the lung is slightly disquieting. Again, the possibility of tuberculosis looms, but lymphoma may produce a diffuse nodular involvement and we have seen cases in which quite definite evidence of previous pulmonary lymphoma cleared under x-ray therapy and I tend to hold to this latter interpretation. In such cases there is evidence of diffuse calcium deposition in various areas of the body. Calcification may occur in scarred areas of treated lymphoma, and this finding is not a strong point for tuberculosis in the case under discussion.

We are given evidence of increasing cerebrospinal pressure and meningeal involvement, with possible involvement of the brain proper. A repeated spinal-fluid examination showed a pellicle on standing, this is always suggestive of tuberculosis, but may occur in any fluid with a high protein content. Finally, our dilemma is climaxed by the report of a single acid-fast organism. If this is true it is

positive evidence of concomitant meningeal tuberculosis.

DR LEWIS K. DAHL: One of the students detected the organism in the smear, and its presence was confirmed by several of the house officers.

DR CLARK: One cannot laugh off a definite acid-fast organism, if it was found. May we see the x-ray films?

DR RICHARD SCHATZKI: The majority of the old films are not here. One film taken about three years ago shows for all practical purposes a normal chest. This chest film, taken when the patient entered the hospital, shows fine miliary nodules of approximately equal size scattered throughout both lung fields and rather homogeneously distributed. We have another film taken a month later, which shows that the lesions had not grown since that time. As a matter of fact they look somewhat smaller, but since the patient was then extremely ill, the films could not be taken in the same fashion. Certainly the lesions have not become larger. The skull shows flecks of calcium, which stereoscopically were thought to be in the inner table or in the dura.

DR CLARK: Does the skull show evidence of general decalcification?

DR SCHATZKI: It does not.

DR CLARK: None of the other bones that are seen show any definite evidence of decalcification?

DR SCHATZKI: No.

DR CLARK: I have committed myself to a primary diagnosis of Hodgkin's disease, to which I shall stick and which I believe will be found diffusely. I shall not take the time to discuss other differential diagnoses in detail. We might for a moment think of the possibility of Boeck's sarcoid. It mimics Hodgkin's disease and involves all the tissues in question, but the lack of any hyperglobulinemia and the general course of the disease make that diagnosis unlikely.

Beyond the basic diagnosis comes the question of several complicating factors. In the first place there was a high blood calcium, and the question arises whether this patient had a concomitant hyperparathyroidism. The chemical findings are rather against it. The elevated blood calcium and the high urinary calcium are consistent, but the presence of a relatively high phosphorus and a low phosphatase militate against this diagnosis, as does the absence of decalcification in the bone. Recently, an increasing number of cases of vitamin D poisoning have been reported, particularly in people taking large doses of vitamin D for arthritis. Symptoms have been described similar to those experienced by this patient — namely, drowsiness, polydipsia, polyuria, dizziness and anorexia in conjunction with high blood and urinary calcium and renal insufficiency. I believe that this patient had some degree of vitamin D intoxication, with renal insufficiency, which may have contributed to the extremely high

urinary calcium output. The destruction of bone in any metastatic neoplasm such as lymphoma, however, could in itself produce a high blood calcium and a high urinary calcium. I believe that a combination of these two factors was at play in this particular case. We might, however, have expected more evidence of decalcification of the bones from vitamin D over this long period than is demonstrated.

Did the patient have diabetes insipidus? The polyuria and the polydipsia were not so extreme as those seen in some cases in which the intake ranges from 8 to 10 liters a day. However, an intake of 4 or 5 liters may be consistent with this diagnosis. The hypercalcemia in itself may have been a cause of the polydipsia and polyuria. On the other hand, the response to pitressin suggests a true diabetes insipidus. Hodgkin's disease has been known to involve the hypophysis and to produce this condition. We also know that basal meningitis in itself may cause symptoms similar to those of diabetes insipidus. We have strong evidence that some process was involving the cranium, and I assume that lymphoma was found in the meninges and in the substance of the brain. I think that this process had involved either the hypothalamic region or the hypophysis. It seems likely that, in the terminal stages, the process broke through from the hypothalamic region into the meninges, and that event may have been the start of the meningeal process.

The question whether there was also a tuberculous process, miliary in nature, with lung involvement, remains open. It is a definite possibility, and if there was a positive acid-fast organism, we must assume that tuberculosis was present. Even though tuberculous meningitis may have been present, I shall hold to a lymphomatous involvement in the central nervous system in addition. The kidneys may well have shown some damage—either lymphomatous or on the basis of calcium deposition with secondary infection. The finding of renal calculi would not be surprising. Various areas of metastatic calcification were doubtless found.

DR DONALD S KING: The interesting thing about the x-ray studies is the marked improvement demonstrated in the film. The patient was much better after a month than at the beginning. Dr Schatzki, have we ever seen that appearance with Hodgkin's disease?

DR SCHATZKI: No, we have had patients with disseminated involvement of the lung by Hodgkin's disease, but usually the lesions were larger and not so homogeneous as these.

DR KING: This case was more consistent with miliary tuberculosis than with Hodgkin's disease?

DR SCHATZKI: Yes.

DR KING: It is interesting to see this change because if the patient had had streptomycin as was suggested we should have ascribed the improvement to the streptomycin.

DR ALLAN M BUTLER: Unless this patient was bedridden, which he may well have been for a while, and suffering atrophy of disuse, which the x-ray films do not indicate, the amount of vitamin D given probably would not have caused any trouble. If such a quantity of vitamin D is administered today it should not be given as viosterol but as one of the concentrated preparations.

DR DAVID G COGAN: I was interested in this patient because of the eye changes. They are readily overlooked unless one searches for them specifically. A slit lamp is not necessary to see the changes. They consist of a deposition of white opacities of the cornea in the palpebral fissure adjacent to the limbus, and in histologic sections they stain like calcium. This patient represents one of seven whom I have seen at the request of Dr Albright, all had a high blood calcium, but none of them had hyperparathyroidism unless uremia was also present. Three of these patients had a high blood calcium associated with sarcoid, and the other four had a high blood calcium associated with hyperparathyroidism as well as uremia. It is an interesting finding in patients with hypercalcemia that is not generally recognized.

CLINICAL DIAGNOSES

Miliary tuberculosis
Tuberculous meningitis
Hodgkin's disease
Vitamin D intoxication

DR CLARK'S DIAGNOSES

Hodgkin's disease, with diffuse involvement, including hypophysis and meninges
Superimposed tuberculous meningitis?
Metastatic calcification
Vitamin D intoxication
Diabetes insipidus

ANATOMICAL DIAGNOSES

Tuberculous meningitis
Miliary tuberculosis of lungs
Tuberculosis of left adrenal gland and thoracic duct
Vitamin D intoxication
Metastatic calcification of kidneys and (?) posterior lobe of pituitary body
(Diabetes insipidus)
Malignant lymphoma, Hodgkin's type, of retroperitoneal lymph nodes

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY: Autopsy on this patient showed both Hodgkin's disease and tuberculosis, the tuberculosis being much the more prominent of the two. In fact the only grossly obvious Hodgkin's focus that we found was in the retroperitoneal lymph nodes, which were considerably enlarged. The lungs were peppered with miliary tubercles, all

uch were firm and fibrous, with a minimal nt of caseation. It is quite possible that in utual acute stage they were considerably larger at the time of autopsy and that they actually l, as the x-ray films suggest. Examination of rain showed an extensive tuberculous menin- which Dr Kubik will discuss in a moment. y case of miliary tuberculosis one is always inted in the source. Miliary tuberculosis is not imary disease but is secondary to some older, of the disease. A careful search throughout oody seemed to show only one possible source, left adrenal gland, where a caseous tubercle

has frequently been described following excessive dosage of vitamin D.

DR CLARK: Was there anything in the pancreas?

DR MALLORY: No.

DR CHARLES S. KUBIK: In this case there was extensive exudate chiefly over the base of the brain, with numerous small tubercles, which were easily seen with the naked eye and from which the diagnosis of tuberculous meningitis could be made conclusively at autopsy. The more usual finding is only a small amount of basilar exudate, with little exudate anywhere else, and a number of characteristic tubercles. In practically every case there are

FIGURE 1

omewhat over 1 cm. in diameter was found that was invading a lymphatic vessel in the periadrenal fat. The rest of the tuberculosis seemed to be fresh and acute. The surprise of the autopsy was that the thoracic duct was completely occluded, almost from top to bottom, with caseous material.

The posterior lobe of the pituitary body showed a small lesion, a spicule of dense calcium, one part of which had been slightly organized into bone. This was surrounded by a mass of necrotic polymorphonuclear cells. There was nothing about it to permit a positive diagnosis of tuberculosis. Since calcification was found in other areas there is a possibility that this was a focus of metastatic calcification and not a tuberculous lesion. The kidneys were large, and on gross section innumerable small white specks could be seen, mostly in the pyramids. Sections showed microscopically that these were masses of calcareous material lying close to but always just outside the collecting tubules and occasionally the distal convoluted tubules (Fig 1). The appearance is characteristic of the type of renal calcification that

tubercles of the ependyma of the lateral and third ventricles, particularly the latter. The ventricles are enlarged. On microscopical examination there is likely to be infiltration of the cranial and spinal nerves and, in some cases, of the optic chiasm or tracts. In the case under discussion there was degeneration in one of the third cranial nerves, which probably accounted for the large pupil noted during life. The infection often extends through the arachnoid to the inner surface of the dura and through the pia into the underlying tissues.

CASE 33072

PRESENTATION OF CASE

A forty-eight-year-old married woman entered the hospital because of unexplained fever.

The patient had been well and active until six months before entry, when she began to complain of fatigue. Three months later she developed dyspnea and noticed that she was losing weight. Six

urinary calcium output. The destruction of bone in any metastatic neoplasm such as lymphoma, however, could in itself produce a high blood calcium and a high urinary calcium. I believe that a combination of these two factors was at play in this particular case. We might, however, have expected more evidence of decalcification of the bones from vitamin D over this long period than is demonstrated.

Did the patient have diabetes insipidus? The polyuria and the polydipsia were not so extreme as those seen in some cases in which the intake ranges from 8 to 10 liters a day. However, an intake of 4 or 5 liters may be consistent with this diagnosis. The hypercalcemia in itself may have been a cause of the polydipsia and polyuria. On the other hand, the response to pitressin suggests a true diabetes insipidus. Hodgkin's disease has been known to involve the hypophysis and to produce this condition. We also know that basal meningitis in itself may cause symptoms similar to those of diabetes insipidus. We have strong evidence that some process was involving the cranium, and I assume that lymphoma was found in the meninges and in the substance of the brain. I think that this process had involved either the hypothalamic region or the hypophysis. It seems likely that, in the terminal stages, the process broke through from the hypothalamic region into the meninges, and that event may have been the start of the meningeal process.

The question whether there was also a tuberculous process, miliary in nature, with lung involvement, remains open. It is a definite possibility, and if there was a positive acid-fast organism, we must assume that tuberculosis was present. Even though tuberculous meningitis may have been present, I shall hold to a lymphomatous involvement in the central nervous system in addition. The kidneys may well have shown some damage—either lymphomatous or on the basis of calcium deposition with secondary infection. The finding of renal calculi would not be surprising. Various areas of metastatic calcification were doubtless found.

DR DONALD S KING: The interesting thing about the x-ray studies is the marked improvement demonstrated in the film. The patient was much better after a month than at the beginning. Dr Schatzki, have we ever seen that appearance with Hodgkin's disease?

DR SCHATZKI: No, we have had patients with disseminated involvement of the lung by Hodgkin's disease, but usually the lesions were larger and not so homogeneous as these.

DR KING: This case was more consistent with miliary tuberculosis than with Hodgkin's disease?

DR SCHATZKI: Yes.

DR KING: It is interesting to see this change because if the patient had had streptomycin as was suggested we should have ascribed the improvement to the streptomycin.

DR ALLAN M BUTLER: Unless this patient was bedridden, which he may well have been for a while, and suffering atrophy of disuse, which the x-ray films do not indicate, the amount of vitamin D given probably would not have caused any trouble. If such a quantity of vitamin D is administered today it should not be given as viosterol but as one of the concentrated preparations.

DR DAVID G COGAN: I was interested in this patient because of the eye changes. They are readily overlooked unless one searches for them specifically. A slit lamp is not necessary to see the changes. They consist of a deposition of white opacities of the cornea in the palpebral fissure adjacent to the limbus, and in histologic sections they stain like calcium. This patient represents one of seven whom I have seen at the request of Dr Albright, all had a high blood calcium, but none of them had hyperparathyroidism unless uremia was also present. Three of these patients had a high blood calcium associated with sarcoid, and the other four had a high blood calcium associated with hyperparathyroidism as well as uremia. It is an interesting finding in patients with hypercalcemia that is not generally recognized.

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY: Autopsy on this patient showed both Hodgkin's disease and tuberculosis, the tuberculosis being much the more prominent of the two. In fact the only grossly obvious Hodgkin's focus that we found was in the retroperitoneal lymph nodes, which were considerably enlarged. The lungs were peppered with miliary tubercles, all

rtant then to point out some apparent facts. icide was absent, and for this reason the clinical are was not that of obvious intrahepatic infection, such as an infectious hepatitis. One can be that the infectious process did not develop so dly that jaundice did not have time to appear. duration of the fever and of the hepatic enlargement was several months. It is more reasonable to me that an infectious process would have been ociated with focal areas of infection in the form of luple liver abscesses or possibly a single large cess. It is possible that such a spotty type of ction also involved the vascular bed of the liver, h resulting thrombophlebitis. I am sure that intuous hepatitis was not present. Other acute intions, such as brucellosis, do not seem likely, since : clinical course was quite atypical for brucellosis d agglutination reactions were negative. Infec-us mononucleosis could present such a picture, t the blood studies are distinctly against such a agnosis.

What other possibilities are there? One is a new owth, such as a lymphoma of some sort, Hodgkin's ease of the reticulum-cell type or even leukemia. ny one of these may be associated with hepatic largement and with a fever that simulates sepsis. gainst such a diagnosis was the absence of adeopathy and splenic enlargement and the blood findings. Could the hepatic enlargement and fever have een due to metastatic neoplasm, carcinomatous or therwise? There is no evidence of a malignant esion elsewhere. X-ray studies of the gastrointestinal tract were negative, and there were no abnormalities in the urine. There is no clue regarding the possibility of cancer, so far as I can see, with the possible exception of the bloody chest tap.

Could the patient have had cirrhosis of the liver? In such cases fever, pain and an enlarged liver are observed, but the clinical picture presented in the case under discussion was not, to my mind, at all suggestive of this type of hepatic disease. Even in the presence of a superimposed hepatoma, it seems to me that the febrile course was most unusual and probably against such a diagnosis.

If liver abscess is considered, one must mention the possibility of a solitary abscess, conceivably due to amebic infection. Against such a diagnosis was the lack of response to an adequate dose of emetine. In most cases the therapeutic response to this drug is dramatic, and I therefore believe that such a possibility can be ruled out. Furthermore, no cysts or parasites were found in the stools. If multiple liver abscesses caused the septic fever, their possible source must be sought. In most cases the abscesses are secondary to an infectious process related to appendicitis or infection of the biliary tract. We occasionally see hepatic abscesses associated with ulcerative colitis, but this, of course, was obviously not present in the case under discussion.

There could have been a septicemia with metastatic liver abscesses, but four blood cultures were negative. In my experience, it is unusual to have multiple liver abscesses associated with fever of this type without the frequent recurrence of chills. It seems to me that such a possibility should be considered with, let us say, a thrombophlebitis of the portal radicles or even of the intrahepatic veins or of the hepatic vein itself. If such an infection was present, one must again inquire its source. In most cases the process is associated with thrombophlebitis elsewhere, or with focal infection or malignant involvement of the biliary tract with compression of the venous channels in the liver, either hepatic or portal.

The chest findings indicate only a high diaphragm on the right with fluid in the right pleural cavity and with a tremendous enlargement of the liver. I shall not waste time in discussing the x-ray films, unless there is a suggestion of some other findings.

DR JAMES R LINGLEY: That is all they show.

DR JONES: The description of the abdominal films is quite typical of ascites — that is, a ground-glass appearance with more or less obliteration of the soft-tissue outlines. Am I correct?

DR LINGLEY: Yes.

DR JONES: There were ascites and a right hydrothorax. A chest tap showed 670,000 red cells and 18,000 white cells per cubic millimeter, with 80 per cent polymorphonuclear leukocytes. The presence of blood in the pleural fluid may have been due to trauma to a vein but definitely suggests the possibility of cancer or tuberculosis. I have never seen a clinical picture such as this due to tuberculosis. The fluid in the pleural cavity, I believe, could have been associated with a thrombus of a venous radicle in the region of the diaphragm. Most of the trouble was certainly under the diaphragm, and a subphrenic abscess was properly suspected. The patient was tapped in the twelfth interspace and also anteriorly to determine if pus could be located under the diaphragm. So far as the x-ray study is concerned, there could have been a subphrenic abscess with irritation in the pleural cavity above, but such a process does not explain the obvious hepatic enlargement. It is evident that I am groping for an explanation of a mysterious clinical picture.

I have one or two other comments. There is not too much information in the record about liver function, but the fact that the prothrombin time was prolonged suggests that the liver was seriously damaged. There are other factors, such as diarrhea, to explain the prolongation of the prothrombin time. The serum albumin and protein were low. These figures could go with interference with hepatic function and help in part to explain the accumulation of fluid in various parts of the body. They do not have diagnostic significance, however. If straightforward infection had been present in or around the

weeks before entry a physician discovered that she had anemia, the white-cell count was 25,000, with an increase in polymorphonuclear leukocytes. The temperature was normal at that time. Two weeks later she developed night sweats and a temperature swinging up to 105°F. She was admitted to a hospital, where the liver edge was thought to be palpable one fingerbreadth below the costal margin, it was not tender. The red-cell count was 2,800,000, with a hemoglobin of 47 per cent, and the white-cell count 20,000 to 40,000. The sedimentation rate was elevated. A blood culture yielded *Alcaligenes* (type undetermined). The urine showed a + test for albumin, and the sediment contained occasional white cells. There was no urobilinogen. The icteric index was normal. A cephalin-flocculation test gave a + reaction, and the alkaline phosphatase was 5.2 Bodansky units. Agglutination tests for typhoid, brucellar and heterophil antibodies were negative. X-ray films of the chest and of the gastrointestinal tract and a pyelogram were normal, as was an electrocardiogram. Examinations of the stools for amebas were negative. For four weeks before entry the liver increased progressively in size, with occasional bouts of soreness, and the temperature ranged from subnormal to 105°F. During the periods of high temperature the patient was frequently disoriented. With a fluid intake of 2400 to 4000 cc, the urinary output ranged from 300 to 900 cc. Neither 11 gm of sulfadiazine over a forty-eight-hour period nor 3,480,000 units of penicillin administered in two courses of eight days each had any effect on the temperature. An eleven-day course of sodium salicylate, with a total daily dosage of 7 to 60 gm, held the temperature below 102.4°F. This therapy was terminated because of a drop in urinary output. No further reduction in the temperature was obtained with 40 mg of intramuscular emetine hydrochloride given intramuscularly, and the patient grew progressively worse. A week before entry she had slightly icteric scleras and bile in the urine for a day. She also developed slight edema of the ankles and sacrum. Since the onset of the illness, she had lost about 10 pounds in weight.

On admission to this hospital the patient was moderately disoriented, drowsy, dyspneic and dehydrated. The scleras were slightly icteric. There was no palpable lymphadenopathy. The right leaf of the diaphragm was elevated to the inferior angle of the scapula. There were dullness, diminished breath sounds and a few crackling rales over the lower half of the right chest. The heart sounds were rapid and forceful. A Grade II systolic murmur was heard over the precordium. The abdomen was tense and distended. The liver edge was palpable 4 to 5 cm below the costal margin and was extremely tender. The spleen could not be felt. There was no fluid wave or shifting dullness. There was moderate edema over the ankles.

The temperature was 101.5°F, the pulse 110, the respirations 27. The blood pressure was 111/80, systolic, 68 diastolic.

Examination of the blood showed a hemoglobin of 10.6 gm and a white-cell count of 20,600, with 65 per cent neutrophils. The nonprotein nitrogen was 18 mg, and the serum protein 5.7 gm per 100 cc, with an albumin globulin ratio of 1.17, the cholestrol was 92 milliequiv per liter. The prothrombin time was 39 seconds (normal, 19 to 21 seconds), the serum van den Bergh and the blood Hinton reaction were negative, as were four blood cultures. The urine was normal except for a + test for albumin.

X-ray examination revealed a high diaphragm on the right, obscured by increased density in the lower lung field. There was also evidence of fluid extending upward along the lateral chest wall. Beneath the right half of the diaphragm there was a ground-glass density extending down to the right lower quadrant of the abdomen. The right lobe of the liver appeared to reach almost to the iliac crest. The soft-tissue outlines of the entire abdomen were partly obliterated by increased density. No gas was seen in or about the area of the liver. There was no evidence of dilated loops of bowel.

On the third hospital day the right side of the chest was aspirated high in the axilla, and 50 cc of blood fluid containing 670,000 red cells and 12,800 white cells per cubic millimeter was obtained, 80 per cent of the white cells were polymorphonuclear. Aspirations under the twelfth rib posteriorly and under the costal margin anteriorly were negative.

On the fifth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR CHESTER M. JONES. It is obvious that since this patient was operated on she was thought to have a surgical condition that was remediable. I do not believe that she was operated on solely for diagnosis. The history that she presented was one of gradual weakness and a spiking temperature that slowly increased in severity, but she had no chills at any time. The liver enlarged rather rapidly and was tender, but there was no associated jaundice. During the course of the disease, fluid developed in various parts of the body, with edema of the extremities, hydrothorax and probably ascites. There was a considerable leukocytosis, the white-cell count varying from 20,000 to 40,000 cells, always with 80 per cent neutrophils. There were no comments regarding either the presence of toxic granules or any abnormality in the type of white cells seen.

With a spiking temperature such as that noted in this case, the question must always be raised concerning the underlying mechanism. If infection, what type of infectious process could it have been? If not infection, what other process could have given such a persistent elevation of temperature? It is

THE ALCOHOLIC PATIENT

EVER since man first observed the phenomenon of fermentation and noted the effect of its products on the human body, he has been faced with the problem of alcoholism. Only in recent years, however, and still far from fully, has the victim of alcohol, like the sufferer from mental disease, been considered as an ill person.

The consumption of strong drink is again on the increase, and with it we are undergoing a resurgence—we hope a more intelligent one than ever before—in our concern for the drunkard. Contributing to knowledge of the subject is the report issued in 1945 by the special commission appointed by the Legislature to investigate the problem of alcoholism in Massachusetts.

There are now, it is estimated, some 20,000 alcohol addicts in the Commonwealth, and alcohol is largely responsible, in one way or another, for the commitment of 25 per cent of the population of our mental hospitals, in addition, alcoholism is responsible for 26 per cent of the cases handled by the Boston Council of Social Agencies. Alexander, Moore and Leary* found on an analysis of all deaths due to toxic substances from 1928 to 1937 that ethyl alcohol was the cause in 52 per cent.

Eighty out of every hundred prisoners in the Charles Street Jail, according to a recent report, are under arrest for drunkenness, and His Honor, Mayor James M. Curley, has made the sagacious suggestion that the jail be converted into a hospital for alcoholic patients, the cost of its maintenance to be met by increasing the license fee for the sale of alcoholic beverages by \$500 annually.

The proposition that those who profit by the sale of liquor be made at least partly responsible for the cost of its by-effects seems fair. It recognizes also the thesis that alcoholism is a medical rather than a penologic problem. As evidence that an enlightened view of alcoholism is not universal comes a statement from the Massachusetts Commissioner of Probation and others urging repeal of the statute allowing persons arrested for drunkenness to be released without punishment for the first four offenses. With alcoholism considered as a disease, the word "punishment" is objectionable.

The Charles Street Jail, obviously, is scarcely a suitable building for a hospital, nor is it yet clearly demonstrated that more in-patient facilities are required for alcohol addicts. If such a need can be demonstrated, the recently proposed program calling for the utilization of the Bridgewater State Farm is more to the point and deserves careful scrutiny. There is no question that more clinic facilities of one sort or another are necessary.

What is definitely in order is a recognition of the facts, by the medical profession, as well as by others, that alcoholism is a disease, that, as with other diseases, its prevention is more effective than its cure and that the place of the physician is with the various agencies that are striving toward that end.

*Alexander, L., Moore, M., and Leary, T. Deaths from poisoning—incidence in Massachusetts. *J. Crim. Psychopathology* 3:100-111, 1941.

liver, one would expect marked toxic granulation in the white cells. No such observation was made. I believe that it is possible, therefore, to veer away from focal infection in the liver but not from infection adjacent to the liver. I have already suggested the possibility of thrombophlebitis, and I think that there were areas of thrombophlebitis in the portal circuit, in the body of the liver itself or in the hepatic veins at the entrance of the vena cava. I have a suspicion that something like Chiari's syndrome may have been present. This curious clinical picture is always secondary to another process — sometimes an infection and sometimes a metastatic neoplasm infiltrating the liver and compressing the venous channels. I am inclined to doubt a really diffuse infiltrating cancer in the liver because of the complete absence of jaundice. I am more inclined to think that there may have been a malignant process outside the liver. At a guess, I suggest that it might have been a lymphomatous type of neoplasm. I do not believe that there was a single hepatic abscess or multiple hepatic abscesses or that operation was performed with the expectation of finding focal sepsis in the liver. The failure to obtain a therapeutic response from penicillin in no way rules out intrahepatic infection, because undrained sepsis in the liver will not respond satisfactorily to antibiotics.

So far as I am concerned, the absence of chills makes me believe that a primary infectious process in the liver was not present. Pylephlebitis, of course, is a possibility, but I cannot imagine what the initial cause was.

Finally, therefore, I lean to the possibility of some neoplastic disease around the liver, causing its rapid enlargement and fever but little serious interference with liver function. I shall leave it there, but merely add that I believe that what was found at operation was not amenable to surgery.

DR WADE VOLWILER: I was asked to see this patient to consider the possibility of doing a blunt-needle biopsy of the liver to make a histologic diagnosis. The patient was extremely ill, disoriented and delirious and looked as if she would die at any moment. It seemed, in spite of the absence of chills, that focal infection within the liver was entirely possible and that therefore one would not want to do any procedure that might spread sepsis. Also, the prothrombin time was prolonged, and such a procedure would not be safe without a transfusion.

We went for the argument in favor of infection — hook, line and sinker.

DR BEVERLY T. TOWERY: Is not the absence of jaundice against Chiari's syndrome?

DR JONES: No, Kelsey and Comfort* have reported 20 cases in only a small number of which jaundice was present. The syndrome can occur perfectly well without jaundice.

CLINICAL DIAGNOSIS

Liver abscess?

Subphrenic abscess?

DR JONES'S DIAGNOSIS

Neoplastic disease around liver, with intrahepatic thrombophlebitis.

ANATOMICAL DIAGNOSIS

Metastatic epidermoid carcinoma of liver, primary source undetermined

PATHOLOGICAL DISCUSSION

DR TRACY B. MALLORY: I do not know whether the Pathology Department is able to explain this case completely. We can, however, state the major diagnosis. The patient was operated on, as Dr Jones suspected, in the hope that a subdiaphragmatic or liver abscess would be found. For the reason the exploration was done posteriorly, the surgeon came down on the superior surface of the liver, which was studded with tumor masses of metastatic carcinoma. A biopsy was performed. The tumor was highly undifferentiated, but I believe that it was an epidermoid carcinoma. This histologic structure was quite consistent with a bronchiogenic carcinoma, but the patient left the hospital without our ascertaining the primary focus.

DR JONES: Do you agree that there might have been enough infiltration into the hepatic substance or around it to produce a partial venous block, thus causing many of the symptoms noted?

DR MALLORY: That is possible but unusual for metastatic carcinoma. In primary liver-cell carcinoma, venous invasion is frequent, and there is reason why it could not occur with metastatic disease.

DR JONES: If I remember correctly this is just what happened in several cases of metastatic carcinoma reported by Kelsey and Comfort.

COMMENT

Diphtheria was at the highest prevalence for the month of 1935, the number of cases being more than four times the number recorded in December, 1945. Nearly 60 per cent of cases were reported from Boston. Diphtheria tuberculosis was at the highest level since 1942, well below the median for the past seven years. The late seasonal peak kept poliomyelitis above both the average for December, 1945, and the median for the seven-year period. Chicken pox, scarlet fever and whooping cough are just beginning to show trends toward higher levels. Only whooping cough, however, has risen above the median. There has been a decline in the reporting of gonorrhea and syphilis, the former reaching the lowest level since 1942 and attaining the lowest since 1929. Acillary dysentery, measles and mumps were at low levels in the month.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anthrax was reported from Peabody, 1, total, 1. Diphtheria was reported from Boston, 51, Bridgewater, Brockton, 5, Greenfield, 2, Leominster, 2, Lowell, 3, Northampton, 1, Methuen, 1, New Bedford, 4, Palmer, 7, Salem, 1, Somerville, 5, Tewksbury, 2, Wakefield, 1, Waltham, 1, Worcester, 1, total, 88. Dysentery, bacillary, was reported from Newton, 1, Northampton, 1, Springfield, 1, Wrentham, 1, total, 4. Lymphocytic choriomeningitis was reported from Cambridge, 1, Medford, 1, total, 2. Malaria was reported from Braintree, 1, Fall River, 1, East Barrington, 1, Greenfield, 1, Murphy General Hospital, 1, Somerville, 1, Worcester, 1, total, 7. Meningitis, meningococcal, was reported from Boston, 3, Foxboro, 1, Easton, 1, Fall River, 2, Leominster, 1, Waltham, 1, total, 9. Meningitis, Pfeiffer-bacillus, was reported from Boston, 2, Northampton, 1, New Bedford, 2, Rehoboth, 1, Worcester, 2, total, 8. Meningitis, pneumococcal, was reported from Boston, 1, Northampton, 1, Cohasset, 1, Foxboro, 1, Northampton, 1, Worcester, 2, total, 7. Meningitis, undetermined, was reported from Medford, 1, North Adams, 1, total, 2.

Poliomyelitis was reported from Ashburnham, 1, Athol, 1, Boston, 1, Blackstone, 1, Brookline, 2, Fall River, 2, Fitchburg, 1, Framingham, 1, Groveland, 1, Montague, 1, New Bedford, 3, Newton, 1, Taunton, 1, Wellesley, 1, total 18.

Salmonella infections were reported from Boston, 2, Chelsea, 2, Haverhill, 2, Lowell, 2, Melrose, 2, total, 10.

Septic sore throat was reported from Amesbury, 14, Arlington, 1, Boston, 14, Lawrence, 1, Mansfield, 1, Merrimack, 5, Salem, 1, Williamstown, 1, total, 38.

Trichinosis was reported from Cambridge, 1, Falmouth, 1, Framingham, 1, total, 3.

Tularemia was reported from Boston, 1, Tisbury, 1, total 2.

Typhoid fever was reported from Leominster, 1, Marblehead, 1, Salem, 1, total, 3.

Undulant fever was reported from Uxbridge, 1, Wellesley, 1, total, 2.

CORRESPONDENCE

PENICILLIN TREATMENT OF SYPHILIS

To the Editor: Relative to the excellent and timely editorial "Syphilis and Penicillin" which appeared in the December 26 issue of the *Journal*, I should like to call attention to certain parts of it that are at variance with the instructions for the use of penicillin in the state co-operating venereal disease clinics, which are as follows:

All patients with early infectious syphilis (primary, secondary and infectious relapses) and pregnant women with syphilis should be treated with 40,000 units of penicillin given intramuscularly every three hours, night and day, for seven and a half days or until a total of 2,400,000 units has been received, with 0.2 gm. bismuth subsalicylate (1.5 cc. Stabisol) on the first, third, fifth, seventh and ninth days. A Herxheimer reaction, with malaise and fever a few hours after onset of treatment, is to be expected in the majority of cases, but a generalized reaction of this nature is no reason to discontinue treatment.

Serologic and clinical follow-up should be done at the termination of treatment, every month for the first six months and quarterly thereafter until the end of the first year. If the serologic and clinical follow-up is negative the patient should be discharged and advised to return once a year for check-up for the next five years.

In penicillin-treated cases of syphilis in which the periodic serologic and clinical follow-up indicates a relapse the patient should be treated with 4,800,000 units of penicillin, given in 80,000-unit doses intramuscularly every three hours, night and day, for seven and a half days, with 0.2 gm. bismuth subsalicylate (1.5 cc. Stabisol) on the first, third, fifth, seventh and ninth days, unless contraindicated.

In cases in which periodic serologic and clinical examination gives evidence of resistance after the termination of the second course of penicillin, the patient should be referred to the Division of Venereal Diseases, Department of Public Health, for consultation as to further treatment.

All patients with late syphilis are being treated on a consultative basis, the consultation forms being reviewed by Dr. Solomon and his group at the Boston Psychopathic Hospital. This service is available to the private practitioner as well as to the co-operating clinics, and a request to this department should be made for further information on the same. This method of handling the treatment of patients with late syphilis is extremely valuable not only to the patient but also to the physician. Incidentally, there is available to co-operating clinics as well as to private practitioners consultative information for infants and children who are infected with or suspected of having syphilis. Further information may be had by applying to this department.

This information is presented so that private practitioners and possibly the chiefs of the co-operating clinics who receive the *Journal* will not be confused.

RETIREMENT PROGRAM FOR HOSPITAL EMPLOYEES

IN THESE days when nonprofit hospitals throughout the country are faced with varied difficulties in obtaining suitable employees, any constructive plan that has for its object the improvement of working conditions for these workers deserves serious consideration. Recently, Mr. John H. Hayes, president-elect of the American Hospital Association and chairman of its Pension Committee, has announced a retirement program for employees in nonprofit hospitals. He points out that hospital workers are not now covered by benefits of the Social Security Act and that this is one reason why hospitals are at a disadvantage in maintaining a high grade of personnel. In the preliminary studies of the American Hospital Association, it was found necessary to establish a plan that could be easily fitted in with Social Security payments when and if the federal laws were changed to include workers in hospitals. It was also kept in mind that the contributions should be on a modest basis to fill the needs of both small and large hospitals and that provision should be made for transferring benefits from one hospital to another.

The final plan was developed in co-operation with the National Health and Welfare Retirement Association. It provides for joint employee and employer contributions, the optional provision by the hospital of benefits for past service, fully vested rights for retirement purposes to the employer's contributions and transferability between hospitals that are members of the plan. In case of death the employee's contributions plus interest are paid to his beneficiary. All permanent employees over twenty-five years of age, with one year or more of service, are eligible to join provided that the hospital votes to make the payments on a payroll-deduction basis.

The National Health and Welfare Retirement Association is a nonprofit corporation organized by community chests and various national welfare organizations and licensed under the insurance laws of the State of New York. Mr. Gerard Swope is chairman of the Board of Trustees, which is composed of sixty representatives from all parts of the

country, including all the members of the Pension Committee of the American Hospital Association. The association started operations on October 1, 1945, and employer-employee contributions already being received at the annual rate of \$2,000,000.

It is believed that this scheme may well be a useful step in re-establishing better relations between hospital employees and employers. It should be of assistance in attracting a better class of workers to fill these much needed positions.

MASSACHUSETTS MEDICAL SOCIETY BUREAU OF CLINICAL INFORMATION

All secretaries of various medical groups, such as special societies and alumni associations, are requested to notify the Bureau of Clinical Information regarding scheduled meetings, annual dinners and so forth. If such data are on file, it is hoped that duplication of dates can be avoided.

DEATHS

HARE — Charles H. Hare, M.D., of Boston, died January 21. He was in his eighty-fifth year.

Dr. Hare received his degree from Harvard Medical School in 1889. He became interested in gynecology and limited his practice to that specialty, having retired more than a decade ago. He was a member of the Boston Obstetrical Society and a fellow of the American College of Surgeons and the American Medical Association. During his period of active practice he had been a member of the staffs of the First Hospital for Women, Massachusetts Women's Hospital, Elizabeth's Hospital, Boston Dispensary, Carney Hospital and Quincy City Hospital.

PHILLIPS — Wilson F. Phillips, M.D., of Dorchester, died January 29. He was in his seventy-fifth year. Dr. Phillips received his degree from Boston University School of Medicine in 1898. He was a fellow of the American Medical Association. His widow survives.

SHEFFERD — Jeannette M. Shefferd, M.D., of River, died October 25. Dr. Shefferd received her degree from Creighton University School of Medicine, Omaha, Nebraska, in 1912. She was a member of the New England Otological and Laryngological Society and a fellow of the American Medical Association.

TILDEN — Irving N. Tilden, M.D., of Massachusetts, died November 3, 1946. He was in his seventy-sixth year. Dr. Tilden received his degree from Harvard Medical School in 1899. He was a former councilor of the Massachusetts Medical Society and was a fellow of the American Medical Association. His widow and a son, Dr. Benjamin R. Tilden, of Massachusetts, survive.

ator Prosthesis Anatomic and physiologic considerations principles of alignment and fitting designed for the arm and limb manufacturer By Atha Thomas, M D, and R C. Haddan 8°, cloth, 305 pp, with 207 illustrations Philadelphia J B Lippincott Company, 1945 \$8 00

ld War II, like all wars, produced a revival of interest in prostheses. More than 15,000 members of the armed forces of the United States lost an arm or a leg. But it is not generally appreciated that forty thousand amputations, requiring prostheses, are carried out in this country every year. In the services the liaison among

cluding a discussion of the use of Tridione. The book should prove of value to all persons coming into contact with sufferers of epilepsy and migraine.

How A Baby Grows A story in pictures By Arnold Gesell, M D, director, Clinic of Child Development, Yale University 4°, cloth, 80 pp, with over 800 photographs arranged and interpreted with the assistance of Katherine G. Walden, A.B. New York and London Harper and Brothers, 1945 \$2 00

This new type of book consists of an atlas, with a simple, explanatory text, tracing the changes in a child's develop-

The Journal lacks extra copies of the February 21, October 3 and November 14, 1946, issues. If any subscribers who do not bind their copies have the above-mentioned issues on hand, the Journal will gladly pay 15 cents for each copy left at or mailed to its office (8 Fenway, Boston 15).

geon, physical therapist and limb fitter is close and efficient, in civil practice it is not infrequently casual and ineffective. This book, written jointly by a well known surgeon and by the president of the Association of Limb Manufacturers of America, should go far toward bridging this gap. It fills a long felt need in presenting in one profusely illustrated and well written volume the essentials of modern management of amputations. The extensive British experience at Roehampton between the two wars is freely drawn on, and an excellent bibliography is appended to each chapter.

n the Doctor's Office The art of the medical assistant By Esther J. Parsons Illustrations by Jean McConnell 12°, cloth, 300 pp., with illustrations Philadelphia J B Lippincott Company, 1945 \$2 00

This manual, which was written primarily for the physician's assistant, the receptionist, secretary, nurse and laboratory technician, discusses in detail her relations with the physician and his patients. The important subjects of handling patients in the office and the conduct of telephonic service are considered frankly, as well as the personality, character and health of the assistants. The care of office equipment, the keeping of records, office bookkeeping and correspondence are discussed. An important chapter on emergency care in the absence of the physician is included. The material is well organized, and the text well written in an easy style. The type is large and printed on a good soft paper, easy to read and to handle. This manual should prove profitable to both physicians and assistants.

ment during the first five years of life. The pictures are arranged to show instantly and vividly how the infant grows from day to day and month to month and why he acts as he does. Part one shows how the baby gains control of his body, and part two portrays the growth of his mental abilities and personality. The pictures, which are based on the average trends of development, do not portray individual variations.

Trauma of the Central Nervous System Proceedings of the Association for Research in Nervous and Mental Disease, December 17 and 18, 1943, New York 8°, cloth, 679 pp, with 243 illustrations and 44 tables. Research Publications, Volume XXIV Baltimore The Williams and Wilkins Company, 1945 \$8 00

This volume contains twenty-seven papers concerning trauma of the head and brain. The first paper, by Dr. Fred A. Metler, is a history of cranial trauma from the earliest times to the nineteenth century. The other papers are devoted to the physiology, histology, pathology, diagnosis and aftereffects of head injuries. This volume should be in all medical libraries and should prove of value to surgeons interested in brain surgery.

New Drugs By Arthur D. Herrick With a foreword by Austin E. Smith, M.D., secretary, Council on Pharmacy and Chemistry, American Medical Association 8°, cloth, 303 pp. New York Revere Publishing Company, 1946 \$4 00

The title of this new book is misleading, since it does not list and consider new drugs but concerns the regulation of new drugs under federal and municipal control. The first part of the book consists of a thorough analysis of the federal Food and Cosmetic Act of 1938 as it relates to drugs and discusses thoroughly the testing of new drugs for the purpose of determining their safety. The various legal procedures relating to the act are briefly outlined.

An appendix of four parts includes a report of the Secretary of Agriculture on deaths due to elixir sulfanilamide. This report was made in response to Senate Resolution 1944 of November 16, 1937, and was published as Senate Document No. 124, 75th Congress, 2nd Session. During September and October, 1937, at least seventy-three persons died as a direct result of taking the elixir. Twenty other persons died, but the exclusive responsibility of the drug was not established. The ninety-three deaths occurred in fifteen states reaching from Virginia to California. Two hundred and forty gallons were manufactured in Tennessee, and owing to the diligence and quick action of the Food Drug Administration the entire amount of unused elixir was retrieved, and this serious

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Science and Seizures New light on epilepsy and migraine By William G. Lennox, M.D., Sc.D. (hon.), assistant professor of neurology, Harvard Medical School, and visiting neurologist, Boston City Hospital. Second edition 12°, cloth, 258 pp., with 10 illustrations. New York Harper and Brothers, 1946 \$2 00

The first edition of this popular book on epilepsy was published in 1941, and since that time it has been found necessary to make seven reprintings. In this second edition, the section dealing with medication has been rewritten, in-

BOOK REVIEWS

Pediatric X-Ray Diagnosis. A textbook for students and practitioners of pediatrics, surgery and radiology. By John Caffey, M.D. 4th ed., cloth, 838 pp., with 710 illustrations. Chicago: The Year Book Publishers, Incorporated, 1945. \$12.50.

The publication of Caffey's volume fulfills a need of long standing for a text and reference for both pediatrician and radiologist. The volume, based on twenty years' experience at the Babies' Hospital, is divided into the following six sections: "The Head and Neck," "The Thorax," "The Abdomen and Gastro-Intestinal Tract," "The Pelvis and Genito-Urinary Tract," "The Extremities" and "The Vertebral Column." Each section opens with a description of the normal roentgenologic appearance, and this is one of the valuable features of the book. The description of the various pathologic processes is thorough, although there are some rather important omissions, and the text is lucid and eminently readable. The reproductions and drawings, which are used freely, are excellent. The general format is satisfactory, and the bibliography adequate.

This book is recommended without hesitation for the library of every radiologist and pediatrician.

Large Scale Rorschach Techniques. A manual for the group Rorschach and multiple choice test. By M. R. Harrower-Erickson, Ph.D., and M. E. Steiner, M.A. 8th ed., cloth, 418 pp., with 157 tables. Springfield, Illinois: Charles C. Thomas, 1945. \$8.50.

The Rorschach (ink-blot) test for mental rating in its group application, originally designed for the military purposes of selection, classification and rehabilitation of personnel, is discussed in detail in this volume. The first part comprises a brief history of the development of the group procedure, its uses and its technical administration. The second is devoted to an experimental investigation on 340 subjects, providing 8526 responses. The results are presented in both graphic and tabular form. The third describes the multiple-choice test derived from the large mass of experimental material. This short, objective test is designed for the use of psychologists, psychiatrists, educators, social workers and probation officers without any Rorschach training. In this part will be found special chapters on military psychiatric differentiation. The fourth part is composed of lists of the content of responses, intended for reference purposes.

Plaster of Paris Technique in the Treatment of Fractures and Other Injuries. By T. B. Quigley, M.D. 8th ed., cloth, 107 pp., with 103 illustrations. New York: The Macmillan Company, 1945. \$3.50.

This booklet describes, in a concise manner, the application of plaster of Paris to all parts of the body. Simple methods are given that require no special apparatus. The discussion of padding and of the complications that may arise when plaster casts are used is especially well done. Only one method is presented, which is probably an advantage to the novice, since it often requires long experience to select the most efficient technic for different disabilities. Whereas plaster can be used as described for splinting small joints like those of the finger, tin or aluminum is usually found to be much less awkward to manage.

Plaster technic is described for fractures and other injuries to the limbs only, but the technic can be applied to many other disabilities. This is an excellent book and should prove helpful to those who use this type of treatment.

Our Inner Conflicts. A constructive theory of neurosis. By Karen Horney, M.D. 8th ed., cloth, 250 pp. New York: W. W. Norton and Company, Incorporated, 1945. \$3.00.

This book, by an author who has proved her value as an interpreter of psychiatry, particularly the psychoneuroses, by her ability to present the material clearly and concisely for general reading, follows the tendency that has been characteristic of her writings in the past. The author has a clear concept of the subject and presents it in a comprehensive manner. She points out the harm that neurotic conflicts can inflict on the personality to resolve them, more than rational decision, evasion or the exertion of will power is

necessary. They can be cured only by changing the conditions within the personality that draw the conflict into existence. Dr. Horney's method of doing this is fully expounded, and, willing, however, to take an even broader view of therapy and writes as follows:

Fortunately analysis is not the only way to inner conflicts. Life itself still remains a very effective therapist. Experience of any one of a number of things may be sufficiently telling to bring about personal changes. It may be the inspiring example of a truly person, it may be a common tragedy which, by being the neurotic in close touch with others, takes him out of his egocentric isolation, it may be association with a so congenial that manipulating or avoiding them is less necessary. In other instances the consequent neurotic behavior may be so drastic or of such frequent occurrence that they impress themselves on the neurotic mind and make him less fearful and less rigid.

This, indeed, is sound psychotherapy and a point often overlooked by many writers on the subject. This book is highly recommended.

Pathology of Tropical Diseases. An atlas. By J. E. Ash, M.D., and Sophie Spitz, M.D. 4th ed., cloth, 350 pp., with 94 illustrations. Philadelphia: W. B. Saunders Company, 1945. \$10.00.

This volume presents an array of excellent photographic illustrations of many of the diseases of the tropics. The text that accompanies the illustrations is of uneven quality. That part dealing with pathology is excellent, but other parts are replete with statements that are of doubtful value, misleading or incorrect, and these detract from the value of the book.

The Eternal Ones of the Dream. A psychoanalytic interpretation of Australian myth and ritual. By Geza Róheim, Ph.D. 8th ed., cloth, 270 pp. New York: International Universities Press, 1945. \$4.50.

An anthropologic study from a psychoanalytic interpretation of various Australian myths, this book is divided into an introduction and twelve chapter headings, with a final summary and conclusion. There also appears a page of illustrations of several ritualistic ceremonies, as well as drawings depicting several myths and ceremonial objects. Especially frequent is the presentation and interpretation of native word symbols. This lends a heavy air of technicality to the work but makes for difficult reading to the uninitiated in psychoanalysis. The reasonableness of the author's interpretations depends on the reader's psychoanalytic leanings rather than on objective data. An example is the following statement: "The eternal ones of the dream it is we who deny decay, aggression and object-loss, and who guard eternal youth and reunion with the mother."

General and Plastic Surgery, with Emphasis on War Surgery. By J. Eastman Sheehan, M.D. 8th ed., cloth, 345 pp., with 15 illustrations. New York and London: Paul B. Hoeber, Incorporated, 1945. \$6.75.

This book, which was published in 1945, was not revised until October, 1946, and certain material is outdated by recent developments and concepts. One example is the recommendation that sulfonamide ointments be used in the treatment of burns, and another, that sulfonamide solution be used previous to closure of wounds.

This book, however, which has more to do with plastic surgery and the surgery of trauma than with general surgery, introduces and summarizes certain British contributions that should be of use in this country. Wounds are discussed generally and under the regions of the body in which they occur. An interesting section is devoted to war weapons and their methods of injuring and the injuries thus produced.

The volume is profusely illustrated with carefully selected diagrams and photographs.

Plastic surgeons and those interested in trauma may find this book a useful summary of the treatment of wounds during World War II, particularly the reconstructive aspects. It cannot be called a summary of all the methods developed during the war, however, for the procedures described are largely based on experiences in the Spanish Civil War and with the British in World War II.

TREATMENT OF INJURIES TO THE KNEE JOINT*

CLAY R. MURRAY, M.D.†

NEW YORK CITY

INJURIES to the knee joint may be discussed under the following three headings: diagnosis, treatment of surrounding structures and treatment of the joint itself. The third consideration, which is the most important, is the aspect of treatment which is usually neglected.

The basis of all treatment of the knee joint is an appreciation of the physiology of the knee and of how it is disturbed by injury to the joint. There is a mistaken idea that various ligaments stabilize the knee joint. The only two positions in which the ligaments stabilize the joints in living human beings are complete extension — as when one is standing in military attention — and complete flexion, as when one is in a full squat. These are unusual positions. It is perfectly true that in the cadaver, the ligaments stabilize the knee joint. This discussion, however, applies to the physiology of the knee joint in human beings, not to that in cadavers — in other words, to dynamic anatomy, not static anatomy.

In uninjured persons stabilization of the knee joint in any degree of flexion is accomplished by coordinated muscle action of the surrounding muscles. If, for any reason, that action is disturbed, so that one group of muscles acquires power superior to that of another, the knee joint becomes unstable, whether or not there is any lesion of the joint ligaments. The ligaments serve to prevent gross displacements.

I can state factually what happens when the knee joint is injured, but I cannot adequately explain it. Any injury to the intra-articular portion of the knee joint is associated with a rapid hypotonia that is relatively selective for the extensor mechanism of the joint and involves the rectus and the vasti muscles. The flexor group of muscles is also involved, but to a mild degree. The extensor group is implicated to such an extent that a palpable difference in tone can be demonstrated within two

hours after injury and visible evidence of atrophy is present within five days after injury. This point is too frequently not given adequate weight, mainly because the patient usually rolls up his trousers to disclose the knee joint. No patient should have anything covering his thighs during such an examination; he should be free of obscuring drapery from the hips down so that the thighs can be examined for any visible difference in size or contour, such as flattening of the rectus muscle, and palpated to determine the difference in tone, both in the relaxed state and in that of attempted contraction. The thighs should then be measured, at a definite level above a given anatomic landmark, so that the level will be exactly the same on the two sides. If there is no visible or palpable hypotonia or atrophy and no measurable atrophy, there is probably no lesion involving the knee joint, and it can be assumed that the lesion lies outside the joint. If there is palpable and visible hypotonia and measurable atrophy in the thigh muscles soon after injury, the difficulty lies within the joint. If that fact is remembered, one will already have gone a long way toward clearing up the diagnosis of obscure lesions in the knee joint.

The second point to remember is that any patient who develops fluid in the joint within hours of the injury does not have a traumatic synovitis but has a hemarthrosis. Whatever the diagnosis, it must explain the hemarthrosis. The habit of calling a collection of fluid within the knee joint a traumatic synovitis because no definite abnormality is observed is a serious mistake, because it implies that the joint has merely been irritated and that synovial fluid has collected. Synovial fluid collects in the knee joint over a period of days or weeks as a result of trauma, not over a period of hours. The condition must therefore be explained on the basis of bleeding into the joint.

The third point in diagnosis of these lesions is adequate examination, the first part of which consists in inspection, as pointed out above. Range of extension is a primary consideration. If the patient

*Presented at the annual meeting of the New Hampshire Medical Society, Manchester, May 14, 1946.

†Professor of orthopedic surgery, Columbia University College of Physicians and Surgeons, attending surgeon and chief of Fracture Service, New York Orthopedic Hospital.

epidemic of drug poisoning was brought to an end. Appendix B consists of selected articles bearing on drugs taken from the Federal Drug and Cosmetic Acts and Regulations. Appendix C is a summary of drug legislation now in force in eleven states and in New York City. The work concludes with the official rules of the Council on Pharmacy and Chemistry of the American Medical Association.

This new work should be in the collection of all public, medical and legal libraries and should be valuable for all persons interested in pharmacy and drug manufacturing.

Industrial Toxicology. By Alice Hamilton, M.D., and Rutherford T. Johnstone, M.D., director, Department of Occupational Diseases, Golden State Hospital, California. (Reprinted from *Oxford Loose-Leaf Medicine*, with the same page numbers as in that work.) 8^{vo}, cloth, 65 pp. New York: Oxford University Press, 1946. \$2.50.

This short monograph by recognized authorities summarizes the pathology, diagnosis, treatment and prevention of industrial poisoning. A long bibliography is appended to the text. The publishers in reprinting this important contribution have made it possible for interested persons to have the monograph without subscribing to *Oxford Loose-Leaf Medicine*. The monograph is recommended for all medical and public libraries and to all persons interested in industrial poisoning.

NOTICES

ANNOUNCEMENT

Dr Irving L. Pavlo, having returned from military service, announces the opening of his office at 469 Beacon Street, Boston, for the practice of ophthalmology.

SOUTH END MEDICAL CLUB

The next regular meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, February 18, at twelve noon. Dr Reginald H. Smithwick will speak on "The Surgical Treatment of Hypertension." Physicians are cordially invited to attend.

BOSTON GASTROENTEROLOGICAL SOCIETY

The Boston Gastroenterological Society will hold a luncheon meeting for members and their guests in the Harvard Club on Wednesday, February 19, at twelve noon. Dr Dwight O'Hara will speak on "The Activities of the Massachusetts Medical Society."

NEW ENGLAND SOCIETY OF PHYSICAL MEDICINE

The regular meeting of the New England Society of Physical Medicine will be held at the Hotel Kenmore, Boston, on Wednesday, February 19, at 8 p.m.

PROGRAM

Exercises for Bed Patients, Medical and Surgical. Dr J. Wayne MacFarland, of Washington, D.C., editor of *Life and Health* and vice-chairman on physical medicine, Southern Medical Association.

Physicians, students, physical therapists and nurses are cordially invited to attend this meeting.

NEW ENGLAND PATHOLOGICAL SOCIETY

The next meeting of the New England Pathological Society will be held on Thursday, February 20, at the Beth Israel Hospital, Boston. The afternoon slide seminar will be held at 4 p.m. Dinner will be served at the hospital, and the evening meeting will be held in the auditorium at 8 p.m. Dr Frank W. Foote will speak on the subject "Benign Proliferative Lesions of the Breast."

NEW ENGLAND OPHTHALMOLOGICAL SOCIETY

The three hundred and seventy-fifth meeting of the New England Ophthalmological Society will be held on Wednesday, February 19, at the Massachusetts Eye and Ear Infirmary, Boston.

PROGRAM

9:00 a.m.-12:00 p.m. Operating Clinic. Staff members.
2:30-3:30 p.m. Presentation of cases.
4:00-5:30 p.m. Instructional Course "Pathology of the Conjunctiva."
8:00 p.m. Business Meeting.
8:15 p.m. "Twenty-nine Cases of Rheumatoid Iritis." Dr Lloyd Mills.
8:45 p.m. "The Surgical Treatment of Strabismus in Children." Dr Maynard C. Wheeler, of the Eye Institute, Columbia Medical Center, New York City.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, FEBRUARY 20

FRIDAY, FEBRUARY 21

*9:00-10:00 a.m. The Mechanisms of Hemoglobinuria in Thermal Burns. Dr Thomas Hale Ham. Joseph H. Pratt Diagnostic Hospital.

*10:00 a.m.-12:00 p.m. Medical Staff Rounds. Peter Bent Brigham Hospital.

MONDAY, FEBRUARY 24

*12:15-1:15 p.m. Clinicopathological Conference. Peter Bent Brigham Hospital.

TUESDAY, FEBRUARY 25

*12:15-1:15 p.m. Clinicoröntgenological Conference. Peter Bent Brigham Hospital.

WEDNESDAY, FEBRUARY 26

*9:00-10:00 a.m. The Use of Streptomycin in Tuberculosis. Dr Lowrey F. Davenport. Joseph H. Pratt Diagnostic Hospital.

*11:00 a.m.-12:00 p.m. Medical Clinic. Amphitheater, Children's Hospital.

*12:00 p.m. Clinicopathological Conference (Children's Hospital). Amphitheater. Peter Bent Brigham Hospital.

*2:00-3:00 p.m. Combined Clinic by the Medical, Surgical and Orthopedic Services. Amphitheater. Children's Hospital.

*7:15 p.m. Graduate Seminar in Pediatrics. Children's Medical Service. Amphitheater 3A. Massachusetts General Hospital.

*Open to the medical profession.

TREATMENT OF INJURIES TO THE KNEE JOINT*

CLAY R. MURRAY, M.D.†

NEW YORK CITY

INJURIES to the knee joint may be discussed under the following three headings: diagnosis, treatment of surrounding structures and treatment of the joint itself. The third consideration, which is the most important, is the aspect of treatment that is usually neglected.

The basis of all treatment of the knee joint is an appreciation of the physiology of the knee and of how it is disturbed by injury to the joint. There is a mistaken idea that various ligaments stabilize the knee joint. The only two positions in which the ligaments stabilize the joints in living human beings are complete extension — as when one is standing at military attention — and complete flexion, as when one is in a full squat. These are unusual positions.

It is perfectly true that in the cadaver, the ligaments stabilize the knee joint. This discussion, however, applies to the physiology of the knee joint in human beings, not to that in cadavers — in other words, to dynamic anatomy, not static anatomy.

In uninjured persons stabilization of the knee joint in any degree of flexion is accomplished by co-ordinated muscle action of the surrounding muscles. If, for any reason, that action is disturbed, so that one group of muscles acquires power superior to that of another, the knee joint becomes unstable, whether or not there is any lesion of the joint ligaments. The ligaments serve to prevent gross displacements.

I can state factually what happens when the knee joint is injured, but I cannot adequately explain it. Any injury to the intra-articular portion of the knee joint is associated with a rapid hypotonia that is relatively selective for the extensor mechanism of the joint and involves the rectus and the vasti muscles. The flexor group of muscles is also involved, but to a mild degree. The extensor group is implicated to such an extent that a palpable difference in tone can be demonstrated within two

hours after injury and visible evidence of atrophy is present within five days after injury. This point is too frequently not given adequate weight, mainly because the patient usually rolls up his trousers to disclose the knee joint. No patient should have anything covering his thighs during such an examination; he should be free of obscuring drapery from the hips down so that the thighs can be examined for any visible difference in size or contour, such as flattening of the rectus muscle, and palpated to determine the difference in tone, both in the relaxed state and in that of attempted contraction. The thighs should then be measured, at a definite level above a given anatomic landmark, so that the level will be exactly the same on the two sides. If there is no visible or palpable hypotonia or atrophy and no measurable atrophy, there is probably no lesion involving the knee joint, and it can be assumed that the lesion lies outside the joint. If there is palpable and visible hypotonia and measurable atrophy in the thigh muscles soon after injury, the difficulty lies within the joint. If that fact is remembered, one will already have gone a long way toward clearing up the diagnosis of obscure lesions in the knee joint.

The second point to remember is that any patient who develops fluid in the joint within hours of the injury does not have a traumatic synovitis but has a hemarthrosis. Whatever the diagnosis, it must explain the hemarthrosis. The habit of calling a collection of fluid within the knee joint a traumatic synovitis because no definite abnormality is observed is a serious mistake, because it implies that the joint has merely been irritated and that synovial fluid has collected. Synovial fluid collects in the knee joint over a period of days or weeks as a result of trauma, not over a period of hours. The condition must therefore be explained on the basis of bleeding into the joint.

The third point in diagnosis of these lesions is adequate examination, the first part of which consists in inspection, as pointed out above. Range of extension is a primary consideration. If the patient

†Professor of orthopedic surgery, Columbia University College of Physicians and Surgeons, attending surgeon and chief of Fracture Service, New York Orthopedic Hospital.

is seated, with the heel of the extended leg on the examiner's knee, and told to relax, the knee joint either goes into complete extension or remains in partial flexion. Persistent flexion is due either to muscle spasm or to mechanical blocking in the joint. Flexion caused by muscle spasm may be secondary to fluid in the joint, which can be pushed into full extension without severe pain under slow pressure, on release of the pressure, the knee rebounds into flexion. The normal knee in full extension never rebounds when the pressure is released. If the joint cannot be brought into full extension by steady, slow, continued pressure because of either mechanical obstruction to extension or the severity of the pain occasioned, more than muscle spasm or fluid is involved — there is probably a mechanical derangement of the knee joint.

I find it utterly impossible to make an exact differential diagnosis when confronted with the various mechanical derangements of the knee joint that can occur. A diagnosis of mechanical derangement of the knee joint is made on the basis of the following: a history of injury, hypotonia in the thigh muscles, with or without atrophy, depending on whether hours or days are involved, the rapid accumulation of fluid after injury, and inability to hyperextend the knee joint slowly and gradually into extension, as pointed out above. The injury may be a torn meniscus, a pinched fat pad, which is incidentally a real lesion, or a strain of the ligaments — that is, a mechanical derangement outside the knee joint. Sprains of the ligaments, unless accompanied by hemarthrosis, are not accompanied by hypotonia and loss of thigh contour. When actual ligamentous tears occur they are evidenced by abnormal mobility of the joint in full extension — that is, the leg can be abducted on the thigh if the internal collateral ligament is torn and adducted if the external collateral ligament is torn. In the normal knee, neither abduction nor adduction of the leg on the thigh in full extension is possible, nor is rotation of the tibia on the femur in full extension or forward or backward movement of the tibia on the femur in flexion. The integrity of the various ligamentous structures can thus be tested.

Another frequent lesion is that involving the crucial ligaments, which is a less serious injury than those described above. In the last twenty years this injury was observed at operation in an appreciable percentage of cases, and surgical repair was undertaken in extremely few. I have never seen a patient with a tear of the anterior crucial ligament who, on the basis of a three-year follow-up study, showed any physiologic disturbance of joint function if the quadriceps mechanism had been restored by active treatment, although Dr. John Royal Moore, of Philadelphia, has told me of a case in a boxer, who depended on his footwork for success, in which surgical intervention was necessary.

The posterior crucial, which is the more important ligament, keeps the femur from going unduly forward during weight bearing, the anterior merely keeps it from going backward in hyperextension — an unusual situation. During walking, the tendency is for the femur to slide forward on the tibia when the knees are flexed and weight is borne. The posterior crucial ligament therefore has more functional value than the anterior crucial. The posterior crucial ligament is completely torn when complete dislocation of the knee joint occurs. It is a startling fact that in such dislocation marked instability after reduction and restoration of the muscular mechanism of the thigh is not a characteristic finding.

I therefore recommend much less attention to injuries of the crucial ligaments than is usually accorded them. They represent an internal derangement of the knee joint, without mechanical block. But, more to the point, they represent loss of tone and atrophy in the quadriceps group of muscles, which should be the center of attention for treatment.

Simply because the diagnosis of injury to the knee joint has been made is no reason for an operative procedure. The real physiologic disturbance is hypotonia and atrophy of the quadriceps group of muscles. Attention should be centered on that disturbance.

The number of operations devised to repair ruptures of the crucial ligament is legion. Each one has been devised because the preceding ones have proved to be unsatisfactory. And the end is not yet in sight. The point of attack is wrong, emphasizing a torn structure rather than the physiologic disturbance created by the injury. The less operating done on crucial ligaments and the more attention devoted to restoring tone and power to the quadriceps group, the better off the patient will be. In other words, these injuries, in my opinion, call for constructive conservative therapy — I regard the terms "intelligent" and "constructive," as synonymous.

The diagnostic feature of meniscus injury is a sudden, twisting effort, with the knee flexed, that results in localized pain on the inner or outer side of the knee joint, followed sometimes (but not always) by a rapid accumulation of fluid. Tenderness at the site of the pain, with or without locking of the knee joint, is observed. When the cartilage separates, it may tear loose from its ligamentous attachments to the edge of the tibia, in which event the rupture is through vascular connective tissue. The cartilage may be displaced within the joint. If it remains within the joint, there is a mechanical locking, and the knee will not fully extend because a block of fibrocartilage lies between the tibia and the femur, full extension cannot be obtained, even with an anesthetic. Such a joint must be unlocked. It is pointless to immobilize such a joint in the

locked position. Before it is immobilized, if that form of therapy is to be used, the joint must be unlocked by operation or by manipulation. I do not believe that operation should be performed on a patient with a primary injury until manipulative reduction has been tried. Any manipulation should be done under an anesthetic, for several reasons. In the first place, the patient's muscles must be completely relaxed — otherwise, there is muscle resistance to the manipulation, and failure is probable. Secondly, under anesthesia the manipulation can be more carefully done, repeatedly if necessary, with a minimum of trauma to the joint. Thirdly, the manipulation under anesthesia will not cause pain and distress to the patient, increasing his protective reflex safeguarding the joint and interfering with later functional activity.

The method of reduction is simple. The hip and knee are flexed at right angles. The tibia is rotated loosely inward and outward on the femur in the flexed position, under anesthesia. I prefer intravenous anesthesia because it gives excellent relaxation. Having employed rotation, one loosely abducts and adducts the tibia on the femur in the flexed position. Following this, the knee is brought into sudden extension. The purpose is the same as in shelling peas: the pea is popped out of the pod by pressure between the fingers. The meniscus is the pea, the joint is the pod, and the femur and the tibia are the two fingers. Once the cartilage has been "popped" from its locked position to the periphery of the joint, it cannot go back into the joint as long as the knee is extended.

If the patient's knee is not locked, although he has the signs of a meniscus tear, I believe in radical surgery, in the sense that any procedure undertaken should be complete and thorough. I also believe that any surgeon who performs an unnecessary operation is foolish. No patient with a meniscus lesion whose knee joint is or can be unlocked should be operated on for a first injury. I admit that, on the basis of paper logic, operation is the wisest and most sensible procedure. Once the meniscus is removed, there should never be any more trouble. Perhaps some surgeons never have complications after a knee-joint operation. I sometimes do. Some patients never get pneumonia, or atelectasis or thrombophlebitis and embolism. But some do. Some patients are successful in restoring quadriceps function and stability after operation. But some are not. If the knee joint in a case of primary injury cannot be unlocked the patient should be operated on — not within a week or a month, but as soon as possible.

When the joint can be unlocked or has never been locked and the meniscus is probably involved because of the symptomatology, the knee joint must be kept extended. No activity should be permitted in a patient with a knee joint that is moving, because constant movement will cause continuous damage.

On the other hand, the quadriceps group of muscles is developed solely by exercise. The surgeon seems to be between the devil and the deep sea — the patient cannot exercise his knee, but he must develop his quadriceps.

The problem is not too difficult. The patient must be kept from moving his knee, but he must be made to walk. A plaster or other encasement from ankle to groin in extension does the former, and every hour or oftener, he walks progressively increasing distances without crutch or cane. The substitute for such co-ordinated muscular activity is the quadriceps-contraction exercise — a substitute, but a poor one, because it exercises only the quadriceps group of muscles. What is desired is co-ordinated action by all the muscles of the thigh. When the patient contracts the quadriceps, he selectively exercises a single group of muscles. This is not physiologic quadriceps function. Walking with the knee immobilized must be practiced long enough for the torn ligamentous attachments to reattach, roughly for four weeks, then the plaster is removed, and normal function is started. If the procedure is properly carried out, the patient does not add the atrophy occasioned by disuse to the primary reflex atrophy and hypotonia. He exercises the quadriceps group of muscles as part of a co-ordinated muscle action, and as a result he does not have a weak and atrophied thigh and does not complain that if he turns suddenly his knee "goes out" from under him.

The "giving way" of the knee is usually due not to a residual lesion in the joint but to the facts that muscle support of the joint is inadequate in the quadriceps group and that the joint is thereby rendered unstable. When the plaster encasement is removed the patient is not taught to bend his knee but to develop extensor power, which is where his defect lies. His flexor power is unimpaired.

What is it that makes immobilized joints stiff? There is a good deal of vague and misleading talk about contractions and adhesions. Actually, the patient is suffering from loss of elasticity in and thickening of the capsular structures. This results from loss of efficiency of the minute circulation, secondary to absence of normal muscular activity — the essential factor in maintaining the circulation at an efficient level. A joint does not have to move to remain supple and limber. The muscles that ordinarily move the joint must be kept moving for the minute circulation of the part to approach normal. Ligaments will not be thickened and lose elasticity, leading to stiffness, nor will the mesotenon and paratenon become thick and inelastic secondary to circulatory stagnation.

A tendon does not lie loose and unconnected with the surrounding tissues. It moves because the soft parts — represented by mesotenon or paratenon — are thin, extremely elastic and almost weblike. If they are subjected to chronic vascular stasis, a

cirrhosis is, in effect, produced, with a thickening of the structure and loss of elasticity

The problem is not one of adhesions or contractions but one of circulation, particularly of the minute circulation. That is why normal and co-ordinated muscular activity is so important, apart from its function in the stabilization of the joint.

When the plaster encasement is removed in a case of knee-joint injury, the patient must extend his knee. When he is being taught to walk, instead of being told to be sure to flex the knee at each step, he is instructed to push the knee backward at each step. This is a means of making the quadriceps muscle work. The flexion function returns routinely on normal use.

Straight-leg raising is another excellent method of cultivating extensor function. But the best one is walking, which is a normal and co-ordinated muscle exercise. The patient is not concerned with the action of individual muscles, he practices co-ordinated action of the whole muscle group. (It may sound as though I am making a great deal out of a minor point, this is actually a major point, involving the whole basis of a normal physiologic functional exercise.)

If a patient with a knee joint must be operated on because of the nature of the original injury or because conservative therapy, as described, has failed, what should be done? I have been impressed over the years with the folly and impracticability of making a clear-cut and definite diagnosis in cases of internal derangement of the knee joint. I know that there are those who believe that the definite diagnosis of a single and specific lesion can be made, *I am not among them*.

When a knee joint is operated on for internal derangement, which is as far as I am willing to go in making a diagnosis, I explore the joint thoroughly. I do not make a peephole incision for removal of the meniscus, if that seems the probable difficulty. It can be done simply, of course. Instead, the joint is exposed from top to bottom. I operate without a tourniquet, since I do not believe that temporary anoxemia is of any help to the tissues. A high Trendelenburg position, to further adequate venous return, without a tourniquet, is accompanied by little bleeding.

After a parapatellar incision from the tibial margin to the upper limit of the suprapatellar pouch the patella is displaced to the outer or inner side of the joint. The knee joint is then flexed over the table, enabling visualization of the whole joint and permitting attempts to correct all pathologic conditions observed.

In a series of over 400 cases in which knee joints were so explored, injury to the internal meniscus alone occurred in only 30 per cent. In another 30 per cent at least one other lesion, such as a torn crucial ligament, a lesion of the synovial membrane or a fat-pad lesion, was discovered. In 40 per cent,

from three to nine lesions in addition to that of the meniscus were observed.

Operation in these cases is therefore performed through a long, generous incision, which heals from side to side, not from end to end. The long incision has the same healing time as the short one, and does not entail any difference in postoperative regime from that used with a short incision.

It has been held by some that the knee joint must be kept perfectly quiet postoperatively because movement of the soft parts will interfere with healing. It is interesting that most studies of wound healing are made on the abdominal wall, which is under constant movement twenty-four hours a day with every respiratory movement, it cannot be kept quiet. But there is normally no difficulty in healing of the abdominal wall. It is true that if the patients cough, vomit or sneeze, the wound may not heal properly. The situation is identical in the knee joint. The knee joint can be kept moving but, metaphorically speaking, cannot be allowed to cough, sneeze or vomit. Overpushing of the joint movement, the use of violent or forced exercise, exercise to fatigue limits or beyond pain limits are contraindicated. But healing is aided by movement within physiologic limits. The joint should never be immobilized postoperatively—one of the reasons why knee-joint injuries and operations are associated, in the lay mind, with stiff knees is the fact that for many years it was routine to immobilize knees postoperatively for considerable periods. I am sorry to say that in some places this is still done. If a knee joint is immobilized postoperatively, there must be a valid excuse for the procedure, and the excuse cannot be the problem of wound healing. There is a physiologic limit to the amount of exercise permissible. In general, however, the more exercise obtained for the muscles activating the knee joint within those limits, the better off the patient.

When an injury to the meniscus has cleared up under conservative treatment and the joint is again injured two or three or more months later, the same conservative treatment is not repeated. If the meniscus tear involves the ligamentous structures uniting the meniscus to the margin of the tibia, it will practically always heal under the conservative treatment I have described. If the tear, however, is through the cartilage itself, as in a so-called "bucket-handle fracture," in which the tear runs the length of the cartilage, or if a tab is torn loose from the edge of the cartilage, the chances are that the lesion will never heal. That is a broad statement, but on the basis of all the evidence reported to date, a tear limited to the meniscus will not heal, although it usually heals if it is through the ligamentous structure. If, therefore, under conservative therapy for a supposed torn meniscus the patient becomes free from symptoms, and later has a recurrence of symptoms, it is to be assumed that the tear is through the cartilage and has not healed under

conservative treatment. The patient is then a fit subject for operation

To make assurance doubly sure, is it wise to wait for multiple recurrences before resorting to operation? Such a course is the equivalent of locking the stable door long after the horse has escaped. By the time a patient has sustained such multiple incidents, he has badly damaged the articular cartilage of the joint. Such misguided conservatism simply contributes to progressive damage of the knee joint.

Although I am opposed to operating on a patient with a primary injury of the meniscus if the joint can be unlocked, there is no question in my mind that a second incident, and not the eighth or ninth, is the indication for operation. Conservative therapy is wasted on recurrences of the original injury.

DISCUSSION

DR. EZRA A. JONES (Manchester) I should like to ask concerning the value of treatment with x-rays. Do you think that air injection is of any value? Also, what is the percentage of injuries to the lateral meniscus as compared with those to the medial meniscus, if there is the same damage?

DR. MURRAY On the question of air injection, for the last twenty years, I have tried air injection, oxygen injection and air or oxygen combined with other roentgenographically demonstrable substances. The net result has been to make the problem of injuries to the knee joint doubly confusing, because of the extra shadows that the injection of air and opaque material demonstrates. Recently, in Sweden, a technic was developed by which air is injected and x-ray examination is made by coning down to a small concentrated area, such as the internal meniscus and the intercondylar notch, and the claim is made — I have seen some of the pictures, and I am investigating some of them now — that by that technic more specific abnormalities can be demonstrated. I am attempting to duplicate that story, otherwise, my experience is that all that air injections have done is to confuse the picture.

Regarding the question about the relative percentage of injuries to the internal and the external meniscus, roughly 15 per cent of cases occur in the lateral meniscus. Whenever the diagnosis of a lesion of the internal meniscus is made the joint is thoroughly investigated, 10 per cent of cases are bilateral. About 5 per cent of all meniscus lesions occur in the external meniscus alone.

DR. ALBERT P. LAFRANCE (Laconia) I should like to ask Dr. Murray if, when he encounters an injury of the fat pad, he removes the fat pad extensively or treats the case conservatively, with the idea that the lesion may subside.

DR. MURRAY Fat-pad injuries have the same history that one ordinarily gets with a meniscus lesion. There is tenderness alongside the patella tendon and far forward on the joint line, right at the edge of the patella tendon. All the cases are treated conservatively for the first incident — that is, by resting the joint but at the same time exercising the muscles as described above and by enforced walking in plaster, followed by the development of the quadriceps muscle later. With a second occurrence — in other words, a second pinching incident — the joint is explored, the fat pad is removed and the patient is treated postoperatively as for any knee-joint injury.

A PHYSICIAN I am in accord with the stressing of the restoration of the quadriceps muscle for strength and function. I must admit that I believe in contraction to some extent, in addition to all the other things, such as early motion and normal use. I believe in exercising the quadriceps muscle, especially in teaching the patient to control the muscle while he is still in bed. Actually, I prefer to have the patient do quadriceps exercises preoperatively, to learn to use the muscle, and then learn to walk.

DR. MURRAY The exact criteria employed in this routine should be stressed. As pointed out above, the knee joint should not be permitted to "cough" or "vomit" or "sneeze". By this I meant that premature weight bearing is comparable to coughing or sneezing after abdominal operations.

I like to let patients walk on the third day, I have had some who walked on the second day, and many walk only on the sixth or seventh day. None of them are immobilized. I try to get them to do straight-leg raising, muscle exercises and actual walking.

DR. ROBERT R. RIX (Manchester) A diagnosis of internal derangement of the knee joint should not be lightly made, as Dr. Murray pointed out because it is disconcerting to operate on a knee joint and not find anything. Of course, when a knee joint with a bucket-handle tear is opened, the injury is visible. But if the tear is in the posterior portion of the cartilage, out of sight, it cannot be seen. And it is therefore extremely important to make the diagnosis of the tear in the posterior end of the meniscus, so that the knee joint can be entered with confidence and the cartilage removed.

I want to ask Dr. Murray on what criteria he bases the diagnosis of posterior tear of the meniscus.

DR. MURRAY (closing) The diagnosis is revealed by pain back of the knee joint on attempts to straighten the knee and by a point of tenderness behind the internal collateral ligament. This situation is one of the reasons why an incision allowing complete exploration of the joint is made. The incision starts at the top of the quadriceps pouch and is brought down around the border of and 2.5 cm. away from the patella, and then down practically to the tibial tubercle. The patella is displaced outside or inward. The anterior two thirds of the cartilage can be examined through the incision when the knee joint is fully flexed. The fat pad is then removed — it is completely removed in every knee-joint exploration. Operation is performed specifically for a fat-pad lesion, of course, but the pad is removed as a routine in operation for any other lesion because, if it is out, it can never subsequently be pinched, and because its removal permits a wide view of the joint, which is otherwise seriously handicapped by the fat pad, particularly if it is large.

With a history and a suspicion of a tear that cannot be seen, particularly in cases in which repeated incidents have occurred, the posterior part of the joint is explored. Formerly, such exploration had to be done through a separate incision, alongside the hamstrings. But recently, instead of the parapatellar incision, the incision is begun at the top of the quadriceps pouch and is a semicircular one that comes around the lateral or mesial aspect of the knee joint and forward to the tibial tubercle below the patella. This has two advantages. The skin incision lies over the lateral aspect of the joint, and exercise does not increase the tension on the sutures. The anterior skin flap is dissected forward, and the anterior capsule incision can be made close to the patella. If no lesion of the cartilage is observed, the capsular incision is closed and the joint is opened behind the collateral ligament, the posterior portion of the cartilage being inspected. Thus, only one skin incision — and therefore one source of infection — is involved.

cirrhosis is, in effect, produced, with a thickening of the structure and loss of elasticity

The problem is not one of adhesions or contractions but one of circulation, particularly of the minute circulation. That is why normal and co-ordinated muscular activity is so important, apart from its function in the stabilization of the joint.

When the plaster encasement is removed in a case of knee-joint injury, the patient must extend his knee. When he is being taught to walk, instead of being told to be sure to flex the knee at each step, he is instructed to push the knee backward at each step. This is a means of making the quadriceps muscle work. The flexion function returns routinely on normal use.

Straight-leg raising is another excellent method of cultivating extensor function. But the best one is walking, which is a normal and co-ordinated muscle exercise. The patient is not concerned with the action of individual muscles, he practices co-ordinated action of the whole muscle group. (It may sound as though I am making a great deal out of a minor point, this is actually a major point, involving the whole basis of a normal physiologic functional exercise.)

If a patient with a knee joint must be operated on because of the nature of the original injury or because conservative therapy, as described, has failed, what should be done? I have been impressed over the years with the folly and impracticability of making a clear-cut and definite diagnosis in cases of internal derangement of the knee joint. I know that there are those who believe that the definite diagnosis of a single and specific lesion can be made, I am not among them.

When a knee joint is operated on for internal derangement, which is as far as I am willing to go in making a diagnosis, I explore the joint thoroughly. I do not make a peephole incision for removal of the meniscus, if that seems the probable difficulty. It can be done simply, of course. Instead, the joint is exposed from top to bottom. I operate without a tourniquet, since I do not believe that temporary anoxemia is of any help to the tissues. A high Trendelenburg position, to further adequate venous return, without a tourniquet, is accompanied by little bleeding.

After a parapatellar incision from the tibial margin to the upper limit of the suprapatellar pouch the patella is displaced to the outer or inner side of the joint. The knee joint is then flexed over the table, enabling visualization of the whole joint and permitting attempts to correct all pathologic conditions observed.

In a series of over 400 cases in which knee joints were so explored, injury to the internal meniscus alone occurred in only 30 per cent. In another 30 per cent at least one other lesion, such as a torn crucial ligament, a lesion of the synovial membrane or a fat-pad lesion, was discovered. In 40 per cent,

from three to nine lesions in addition to that of the meniscus were observed.

Operation in these cases is therefore performed through a long, generous incision, which heals from side to side, not from end to end. The long incision has the same healing time as the short one, and does not entail any difference in postoperative regime from that used with a short incision.

It has been held by some that the knee joint must be kept perfectly quiet postoperatively because movement of the soft parts will interfere with healing. It is interesting that most studies of wound healing are made on the abdominal wall, which is under constant movement twenty-four hours a day with every respiratory movement, it cannot be kept quiet. But there is normally no difficulty in healing of the abdominal wall. It is true that if the patients cough, vomit or sneeze, the wound may not heal properly. The situation is identical in the knee joint. The knee joint can be kept moving but, metaphorically speaking, cannot be allowed to cough, sneeze or vomit. Overpushing of the joint movement, the use of violent or forced exercise, exercise to fatigue limits or beyond pain limits are contraindicated. But healing is aided by movement within physiologic limits. The joint should never be immobilized postoperatively—one of the reasons why knee-joint injuries and operations are associated, in the lay mind, with stiff knees is the fact that for many years it was routine to immobilize knees postoperatively for considerable periods. I am sorry to say that in some places this is still done. If a knee joint is immobilized postoperatively, there must be a valid excuse for the procedure, and the excuse cannot be the problem of wound healing. There is a physiologic limit to the amount of exercise permissible. In general, however, the more exercise obtained for the muscles activating the knee joint within those limits, the better off the patient.

When an injury to the meniscus has cleared up under conservative treatment and the joint is again injured two or three or more months later, the same conservative treatment is not repeated. If the meniscus tear involves the ligamentous structures uniting the meniscus to the margin of the tibia, it will practically always heal under the conservative treatment I have described. If the tear, however, is through the cartilage itself, as in a so-called "bucket-handle fracture," in which the tear runs the length of the cartilage, or if a tab is torn loose from the edge of the cartilage, the chances are that the lesion will never heal. That is a broad statement, but on the basis of all the evidence reported to date, a tear limited to the meniscus will not heal, although it usually heals if it is through the ligamentous structure. If, therefore, under conservative therapy for a supposed torn meniscus the patient becomes free from symptoms, and later has a recurrence of symptoms, it is to be assumed that the tear is through the cartilage and has not healed under

formed before permanent changes occur in the vessel walls, should improve the renal hemodynamic state.

It has been argued that since splanchnicectomy does not lower the blood pressure when metal clamps are constricting the renal vessels in dogs, it cannot improve renal circulation in man. Such reasoning is fallacious. How could the blood flow be increased by a sympathetic denervation when a mechanical obstruction still exists? I believe that in hypertension in human beings there is a neurogenic clamp—a more or less continuous vasoconstriction—and that section of the autonomic nerves to the blood vessels removes this neurogenic clamp and prevents further abnormal constriction of the arterioles.

It has repeatedly been proved that in hypertension there is a decrease in renal blood flow, and our work, using inulin and Diodrast, has shown that after splanchnicectomy in such cases the renal blood flow has been definitely maintained despite a reduction in blood pressure.³ This suggests an increase in renal blood flow. Work being carried on at present tends to substantiate this hypothesis. This is considered the rationale for the surgical treatment of hypertension.

SURGICAL PROCEDURES

The surgical technic for the treatment of arterial hypertension differs in various clinics, chiefly in the extent of sympathetic denervation. The least extensive is the subdiaphragmatic splanchnicectomy of Adson⁴ and Craig.⁵ Considerably more extensive is the bilateral supradiaphragmatic splanchnicectomy that I⁶ have been carrying out for the past thirteen years. A somewhat more complete denervation is that of Smithwick,⁷ which really combines the two operations mentioned above. A much more extensive denervation is produced by the nearly total sympathectomy of Grimson.⁸ Just which of these procedures will finally be adopted cannot at present be determined. We have carried out the bilateral supradiaphragmatic splanchnicectomy in over 1500 patients, and are not convinced that additional denervation is necessary.

The operation that we perform consists in the bilateral resection of a long segment of the greater splanchnic nerves. This excision extends from the level of the seventh dorsal vertebra downward through the diaphragm. In many cases traction on the greater splanchnic nerve before it is divided pulls the celiac ganglion up to the diaphragm, so that the excision actually extends to the celiac ganglion. In addition, the lower thoracic sympathetic ganglions—usually, the eighth, ninth, tenth, eleventh and twelfth and frequently the seventh as well—are excised. The bilateral removal of the ganglions, of course, includes the various lesser and least splanchnic nerves arising from them. There is always a dramatic and immediate drop in the blood pressure, which may rise in the course of a few hours to a

normal level. Generally, the pressure fluctuates more or less widely for varying periods of weeks to months before it becomes stabilized. In a few cases the pressure remains normal from the beginning.

The bilateral procedure is carried out at one operation, and the time consumed varies from forty-five minutes to an hour and a half. The patient is not shocked by this procedure, although the blood pressure may drop remarkably. In some cases it is necessary to give Neo-Synephrin during the second half of the operation and occasionally for the first few hours thereafter. Patients are encouraged to sit up at an early date, and most of them are out of bed within a week. When the upright position is first assumed, there may be a postural hypotension. This as a rule corrects itself within a few days. Bandaging of the legs and compression of the abdomen have never been found necessary. The usual stay in the hospital is two weeks following operation. Many patients are able to resume their normal activities five or six weeks following the procedure. In fact, some return to their regular work within four weeks of the operation, but a rest period of four weeks at home is advised.

CRITERIA FOR OPERATION

The selection of patients for the surgical treatment of hypertension has been arrived at by the trial-and-error method. When this type of therapy was first undertaken, nothing was known regarding the possibilities or the end results. We therefore operated on patients for whom today surgery would be refused. Age is a definite factor. The highest percentage of cases with sustained worth-while lowering of blood pressure occurs in patients under thirty years of age. In this age group, favorable results were obtained in nearly 80 per cent of cases. In the older age groups, only about 50 per cent of the patients have shown worth-while continued improvement. The youngest patient operated on for hypertension was eight and the oldest sixty-one years of age. Operation is usually not recommended in patients over fifty-three. Exceptions are occasionally made—for example, relief of symptoms is almost certainly obtained irrespective of lowered blood pressure. We have therefore operated on a few patients of fifty-four to fifty-eight years of age whose symptoms were so incapacitating that relief alone justified the surgical procedure. In these cases symptomatic relief was obtained, but in many the blood pressure was not significantly affected. In one patient over sixty years old, operation was performed because of a rapid loss of vision, with extensive hemorrhages and exudates in both fundi. This patient had complete restoration of vision, which has been maintained over a postoperative period of seven years, although the blood pressure was not significantly affected.

All patients are thoroughly studied in various clinics of the hospital so that the condition of the

RESULTS OF BILATERAL SUPRADIAPHRAGMATIC SPLANCHNICECTOMY FOR ARTERIAL HYPERTENSION*

MAX MINOR PEET, M D †

ANN ARBOR, MICHIGAN

ARTERIAL hypertension, usually designated as essential hypertension, is a highly complex disease syndrome. Its manifestations are many and varied, making a true evaluation of any form of therapy extremely difficult. This is further complicated by the normal progress of the disease, which encompasses the extremes from a fatal termination in a few months to a seemingly benign course of many years. Arterial hypertension is never actually benign, however, and the term should not be used. Sooner or later, damage to the brain, heart or kidneys will surely result. The term "essential" is also a misnomer. The elevation of the blood pressure is not necessary, as was at one time believed, to ensure an adequate blood supply to the various organs of the body in the presence of arteriosclerosis.

Although the disease may principally affect the brain in one patient, the heart in another and the kidneys in a third, in all the common factor is a more or less continuous elevation of the blood pressure, both systolic and diastolic. An increase in the blood pressure — temporary, recurrent or continuous — can, of course, occur with a wide variety of pathologic conditions, such as cerebral trauma, basophilic adenoma of the pituitary body, adrenal tumors, coarctation of the aorta and chronic nephritis. In 1939 Page¹ listed forty-seven conditions causing or associated with an elevated blood pressure. The diagnosis of arterial or essential hypertension is really made by exclusion of all the other conditions that may present a somewhat similar picture. This paper considers only the surgical treatment of what is usually designated as "essential hypertension" and in its severer form, "malignant hypertension."

RATIONALE FOR SURGICAL TREATMENT

The rationale for the surgical treatment of hypertension is dependent on one's conception of the disease, especially of its etiology. No one has yet been able definitely to establish the actual cause of arterial hypertension. I have accepted the renal humoral theory, best demonstrated by the brilliant experiments of Goldblatt,² who has conclusively shown that renal ischemia, or at least interference with its hemodynamic state, produces a continuous elevation of blood pressure without evidence of impaired renal excretion. Numerous workers have

shown that such interference with the blood supply of the kidneys results in an excessive amount of a renal pseudoglobulin called "renin," which reacts with another pseudoglobulin, probably from the liver, named "preangiotonin" (the "renin-activator" of Page¹) to form an active vasopressor substance called "angiotonin." This causes arteriolar constriction of sufficient degree to raise peripheral resistance throughout the body, with consequent elevation of blood pressure.

Numerous causes for a primary renal ischemia may exist, but I believe that in the majority of cases it is of neurogenic origin. It has been demonstrated experimentally that electric stimulation of the splanchnic nerves elevates blood pressure, presumably by constriction of the arterioles in the kidney, with resulting renal ischemia. It is my opinion that in human hypertension excessive stimulation through the splanchnic nerves causes similar changes in the renal hemodynamics. This abnormal stimulation of the splanchnic nerves originates, of course, in the autonomic centers of the brain. The activating stimulus may be psychic, reflex from stimuli originating in various parts of the body or chemical. It is known that normally such stimuli are constantly influencing the sympathetic nervous system. How, then, can one explain the abnormal excessive response, sufficient to cause a renal ischemia? I believe that it is a congenital abnormality in the autonomic nervous system whereby excessive responses are evoked by normal stimuli. In the majority of hypertensive patients this congenital tendency of the autonomic system to over-react — that is, to respond to a given stimulus by either greater or more prolonged vasoconstriction — is apparently inherited.

I believe that Raynaud's disease presents a comparable condition. Here, excessive responses to normal stimuli of the autonomic nervous system result first in repeated abnormal vasoconstriction of the peripheral vessels in the hands and feet. Later, with more continuous constriction, permanent vascular changes leading to gangrene occur. No one doubts the role of the autonomic nervous system in Raynaud's disease, since there is definite visual evidence of vasoconstriction following psychic stimuli or exposure to cold. My hypothesis is that in hypertension similar stimuli acting on the abnormally sensitive autonomic centers for the splanchnic nerves cause a more or less continuous renal ischemia. If this theory is correct, — and there is considerable evidence to support it, — splanchnicectomy, if per-

†Professor of surgery, University of Michigan Medical School, chief Neurosurgical Section, University of Michigan Hospital.

adopted, however. A patient under fifty years of age who has completely recovered from one or more cerebrovascular accidents does not present an unusually high surgical risk. If other findings are favorable, we recommend operation and with a definite hope of preventing another stroke. The presence of severe brain damage, as evidenced by aphasia or hemiplegia, is certainly a contraindication to this operation.

Evidence of cerebral encephalopathy manifest by mental confusion or loss of memory presents a difficult problem in deciding for or against surgery. If the mental changes are recent, especially if they are mild, a complete return of cerebral function to a normal status may be expected following splanchnicectomy. On the other hand, if the mental confusion and loss of memory are marked and of long duration, improvement cannot be expected, and operation is not recommended. Even if the changes are mild but apparently due to small repeated cerebrovascular thromboses, I believe that operation should not be performed.

Obesity is a frequent finding in hypertensive patients but, unless extreme, cannot be considered a definite contraindication to splanchnicectomy. It does, however, place an additional load on the heart which has perhaps already been damaged, and certainly makes the operation more difficult and the convalescence more uncomfortable. We therefore recommend a low-calorie diet and do not generally advise operation until the weight has been significantly reduced.

Malignant hypertension, provided the cardiac and renal damage is not far advanced, is, in our opinion, a definite indication for splanchnicectomy, although in some clinics it is considered a contraindication. We classify as malignant only the cases showing a definite papilledema. The fundusoscopic examination usually reveals hemorrhages, exudates and severe angiospasm. The blood pressure is high, especially the diastolic, and most cases show moderate to severe cardiac and renal damage. Without operation the prognosis in these cases is hopeless, a large percentage of the patients dying within the first year.

In summary, the following are our criteria for operation: a patient below fifty-four years of age, a more or less continuously elevated blood pressure, with a systolic pressure over 170 and a diastolic pressure above 105, a nonprotein nitrogen below 45 mg and preferably below 40 mg per 100 cc, a well compensated heart, and a relatively normal cerebral function. Exceptions are occasionally made, especially in the older age group and in cases with a slightly higher nonprotein nitrogen. These exceptions are generally made because of incapacitating symptoms, such as excruciating headaches, or when there is evidence of an otherwise hopeless malignant hypertension.

CLASSIFICATION OF HYPERTENSION

The evaluation of the surgical treatment of hypertension by bilateral supradiaphragmatic splanchnicectomy involves many factors. This is due to the varied manifestations of the disease. It must be remembered that arterial hypertension is a generalized disease, all organs of the body being affected, in some patients the clinical evidence of cerebral damage predominates, in others the heart is chiefly affected, and in some impaired renal function is the chief concern. Any combination of these may occur to complicate the picture further. In addition, the eye findings may give evidence of severe hypertension without cardiac or renal injury. Symptoms are absent in some patients, but are predominant in others. For these reasons a new classification, based on the dominant finding has been suggested,⁹ as follows:

Group 1 (with early, mild hypertension) These patients are entirely asymptomatic, have normal or slightly abnormal fundi and show no evidence of cardiac, renal or cerebral involvement.

Group 2 (in which symptoms are predominant) All patients in this group complain of symptoms and have mild changes in the retinal blood vessels, but display no evidences of cardiac, renal or cerebral impairment.

Group 3 (in which organic heart disease is predominant) In each case the diagnosis of heart disease is confirmed by either a definitely abnormal electrocardiogram or a teleroentgenogram showing cardiac enlargement, or both.

Group 4 (in which cerebrovascular disease is predominant) Each patient in this group has had one or more previous cerebral accidents.

Group 5 (in which impaired renal function is predominant) Each patient shows diminished concentrating ability and urea clearance values.

Group 6 (with malignant hypertension) These patients have severe neuroretinitis, with a papilledema of 1 diopter or more, and display a rapidly progressive, downhill course.

RESULTS OF OPERATION

The majority of our patients have been studied at postoperative periods ranging from one to twelve years. We do not believe that earlier studies have valuable significance.

Symptomatic relief has been striking. Excruciating headaches, usually suboccipital, marked nervousness and irritability, insomnia and distressing palpitation have been greatly relieved or completely eradicated in 86 per cent of the patients still living. This percentage of improvement has persisted almost unchanged over postoperative periods of five to twelve years. Such symptomatic relief is not necessarily dependent on a significant lowering of the blood pressure or improvement in cardiac or renal function.

heart, kidneys, cerebral blood vessels, and eyes can be evaluated as accurately as possible. The blood pressure is taken in both arms and generally in one leg in the horizontal, sitting and upright positions, but for purposes of comparison with the postoperative group, only the sitting readings are considered. These are made at least three times in each arm at one examination, and during the three days of special studies repeated blood-pressure records are made. Careful eye examination, including the fundi and visual fields, is made in the ophthalmologic department. The cardiac status is determined by the electrocardiogram, orthodiagram and teleoroentgenogram. Due consideration is given, of course, to any pertinent facts in the history suggesting previous cardiac insufficiency, such as nocturnal dyspnea, severe exertional dyspnea and angina. We much prefer a negative cardiac history, since the majority of deaths five to thirteen years postoperatively have occurred in patients giving a definite preoperative history of heart complications. Cardiac decompensation is a definite contraindication to surgery. If the cardiac status improves under bed rest, digitalization and other therapeutic measures, however, operation is recommended in the majority of cases. These patients are warned that although the heart may show marked improvement following splachnicectomy, they must continue to be careful and not overexert themselves or place additional loads on an already damaged heart muscle.

Recent evidence of a coronary occlusion is also a contraindication to surgery. We have, however, operated on many patients with a previous history of coronary occlusion when the cardiac status seemed adequate. The operative risk in such patients is not greatly increased, but the prognosis for a longer postoperative life is poorer.

Gross enlargement of the heart, although definitely increasing the operative risk, is not in itself a contraindication. Many patients with enormous enlargement of the heart have shown striking reduction in cardiac size, even to normal, following the reduction in blood pressure by splachnicectomy.

The renal status is determined by an eighteen-hour concentration test, as well as studies of urea clearance and blood nonprotein nitrogen, and urinalysis. In addition, intravenous pyelograms are made in all cases to rule out gross abnormalities in one or both kidneys. If these are unsatisfactory, retrograde pyelograms are made. Markedly contracted kidneys, polycystic kidneys and a unilateral nonfunctioning kidney are contraindications to splachnicectomy. Evidence of moderate damage from previous pyelonephritis is no longer considered a contraindication, since some patients with this condition have shown satisfactory improvement in the blood-pressure level. Further studies are now being carried out, but a preliminary survey fails to show

any correlation between the amount of damage from pyelitis and the postoperative blood-pressure level.

Decision regarding operability never rests on the maximum water concentration and urea clearance determinations alone. These findings are usually paralleled by the height of the blood nonprotein nitrogen. A nonprotein nitrogen above 45 mg per 100 cc when the patient has been taking adequate amounts of fluid is a definite contraindication to splachnicectomy. It is true that we have occasionally operated when the nonprotein nitrogen was above this level, but these patients have shown only temporary improvement, occasionally lasting for a year, or no improvement. Even a nonprotein nitrogen above 42 mg per 100 cc suggests permanent renal damage and gives a poorer prognosis. We prefer the nonprotein nitrogen to be below 40 mg per 100 cc.

Severe renal complications, as evidenced by a measurable amount of albumin in the urine and red cells or occasional casts in the sediment, do not militate against a good surgical result. A significant number of patients have had gross hematuria, even to the extent of so-called "renal apoplexy", in the majority of cases these signs of renal damage have disappeared after splachnicectomy.

A differential diagnosis between chronic glomerulonephritis and renal disease secondary to hypertension must be made, since the former is not amenable to operation. The clinical and laboratory findings may be identical in the two diseases, and the differential diagnosis may depend on the history. Usually, in chronic glomerulonephritis, there is a history of an acute episode of nephritis, often with generalized edema and albuminuria with a normal blood pressure. In some cases only the repeated finding of albumin in the urine before hypertension is manifest makes possible the diagnosis of a primary nephritis and thus rules out splachnicectomy. Conversely, in early hypertension, the urine is normal.

The so-called "hypertensive toxemia of pregnancy," unless there is a definite history of a preceding nephritis, is not a contraindication for splachnicectomy. Many patients give a history of an elevated blood pressure during pregnancy with a return to normal or at least a marked reduction after delivery, only to have the pressure rise still higher in a subsequent pregnancy and remain definitely elevated after its termination. In most of these cases the hypertension has tended to progress. Some of our most brilliant results following splachnicectomy have occurred in patients in whom pregnancy appeared to be the precipitating etiologic factor.

The question of whether a splachnicectomy should be performed on a patient with a definite history of a cerebrovascular accident cannot be answered arbitrarily. Each case must be judged individually. Certain general rules have been

adopted, however. A patient under fifty years of age who has completely recovered from one or more cerebrovascular accidents does not present an unusually high surgical risk. If other findings are favorable, we recommend operation and with a definite hope of preventing another stroke. The presence of severe brain damage as evidenced by aphasia or hemiplegia, is certainly a contraindication to this operation.

Evidence of cerebral encephalopathy manifest by mental confusion or loss of memory presents a difficult problem in deciding for or against surgery. If the mental changes are recent, especially if they are mild, a complete return of cerebral function to a normal status may be expected following splanchnicectomy. On the other hand, if the mental confusion and loss of memory are marked and of long duration, improvement cannot be expected, and operation is not recommended. Even if the changes are mild but apparently due to small repeated cerebrovascular thromboses, I believe that operation should not be performed.

Obesity is a frequent finding in hypertensive patients but, unless extreme, cannot be considered a definite contraindication to splanchnicectomy. It does, however, place an additional load on the heart which has perhaps already been damaged, and certainly makes the operation more difficult and the convalescence more uncomfortable. We therefore recommend a low-calorie diet and do not generally advise operation until the weight has been significantly reduced.

Malignant hypertension, provided the cardiac and renal damage is not far advanced, is, in our opinion, a definite indication for splanchnicectomy, although in some clinics it is considered a contraindication. We classify as malignant only the cases showing a definite papilledema. The funduscopic examination usually reveals hemorrhages, exudates and severe angiospasm. The blood pressure is high, especially the diastolic, and most cases show moderate to severe cardiac and renal damage. Without operation the prognosis in these cases is hopeless, a large percentage of the patients dying within the first year.

In summary, the following are our criteria for operation: a patient below fifty-four years of age, a more or less continuously elevated blood pressure, with a systolic pressure over 170 and a diastolic pressure above 105, a nonprotein nitrogen below 45 mg and preferably below 40 mg per 100 cc, a well compensated heart, and a relatively normal cerebral function. Exceptions are occasionally made, especially in the older age group and in cases with a slightly higher nonprotein nitrogen. These exceptions are generally made because of incapacitating symptoms, such as excruciating headaches, or when there is evidence of an otherwise hopeless malignant hypertension.

CLASSIFICATION OF HYPERTENSION

The evaluation of the surgical treatment of hypertension by bilateral supradiaphragmatic splanchnicectomy involves many factors. This is due to the varied manifestations of the disease. It must be remembered that arterial hypertension is a generalized disease, all organs of the body being affected, in some patients the clinical evidence of cerebral damage predominates, in others the heart is chiefly affected, and in some impaired renal function is the chief concern. Any combination of these may occur to complicate the picture further. In addition, the eye findings may give evidence of severe hypertension without cardiac or renal injury. Symptoms are absent in some patients, but are predominant in others. For these reasons a new classification, based on the dominant finding, has been suggested,⁹ as follows:

Group 1 (with early, mild hypertension) These patients are entirely asymptomatic, have normal or slightly abnormal fundi and show no evidence of cardiac, renal or cerebral involvement.

Group 2 (in which symptoms are predominant) All patients in this group complain of symptoms and have mild changes in the retinal blood vessels, but display no evidences of cardiac, renal or cerebral impairment.

Group 3 (in which organic heart disease is predominant) In each case the diagnosis of heart disease is confirmed by either a definitely abnormal electrocardiogram or a teleroentgenogram showing cardiac enlargement, or both.

Group 4 (in which cerebrovascular disease is predominant) Each patient in this group has had one or more previous cerebral accidents.

Group 5 (in which impaired renal function is predominant) Each patient shows diminished concentrating ability and urea clearance values.

Group 6 (with malignant hypertension) These patients have severe neuroretinitis, with a papilledema of 1 diopter or more, and display a rapidly progressive, downhill course.

RESULTS OF OPERATION

The majority of our patients have been studied at postoperative periods ranging from one to twelve years. We do not believe that earlier studies have valuable significance.

Symptomatic relief has been striking. Excruciating headaches, usually suboccipital, marked nervousness and irritability, insomnia and distressing palpitation have been greatly relieved or completely eradicated in 86 per cent of the patients still living. This percentage of improvement has persisted almost unchanged over postoperative periods of five to twelve years. Such symptomatic relief is not necessarily dependent on a significant lowering of the blood pressure or improvement in cardiac or renal function.

The blood pressure, both systolic and diastolic, was significantly reduced five to twelve years after splanchnicectomy in 81.3 per cent of the patients still living. There had been no change from pre-operative levels in 12.7 per cent. Over the course of years only 6 per cent had an increase in blood pressure. Many of the patients who died (49 per cent had malignant hypertension) during the post-operative period of five to twelve years had had significant reductions in their blood pressure, but regardless of the addition of these cases to those not showing improvement, there was a worth-while reduction of blood pressure in 46.7 per cent of the entire series.

We consider a blood pressure of 140 systolic, 90 diastolic, normal for patients under forty, and one of 150 systolic, 95 diastolic, normal for those over forty. With these criteria, 20.3 per cent of patients have maintained normal pressure for five to twelve years.

A reduction in blood pressure of over 80 systolic, 25 diastolic, although not to normal, is considered a marked improvement. Such a reduction was maintained for the entire postoperative period of five to twelve years in 26 per cent of cases. A significant improvement (a reduction of more than 40 systolic, 15 diastolic) was maintained in 35 per cent.

Considering the patients whose blood pressure has been reduced to normal and those with marked and significant reductions, there was an over-all improvement in blood pressure in 81.3 per cent of the living patients, and the improvement has been maintained to date, that is, five to twelve years after operation.

The funduscopic findings in cases that before operation showed angiospastic retinitis with or without hemorrhages or exudates now show absence of angiospasm, hemorrhages or exudates in 82 per cent. Papilledema disappeared, and in the 21 patients with malignant hypertension who are still living five to twelve years after splanchnicectomy it has not returned.

The cardiac status showed a similar improvement, which was maintained over the long period of post-operative study, patients with marked enlargement of the heart preoperatively showed a significant reduction in 52 per cent. Symptomatic improvement, evidenced by relief of anginal pain, palpitation and shortness of breath, was striking. Some patients who had had frequent attacks of angina pectoris had been completely relieved, and there had been no return of painful attacks under either excitement or exercise for the several years of postoperative study. In a significant number of patients with abnormal electrocardiograms before operation, including those with angina pectoris, the electrocardiogram returned to normal.

The renal function following splanchnicectomy has shown definite improvement, both in water-concentrating ability and urea clearance. Recent

studies have not been completed, but in an earlier study, 45 per cent showed a return of urea clearance to normal and 44 per cent had improvement in water concentration. Red cells and albumin have disappeared from the urinary sediment.

It should be borne in mind that practically all our hypertensive patients had had modern medical treatment, sometimes for years and under the direction of able internists, before being referred to us for splanchnicectomy. Such medical treatment had failed to prevent further progress of the disease, as evidenced by persistent or increasing blood pressure, continuing of impairment of cardiac or renal functions, advancing eye changes, cerebral accidents and intensified symptoms. Therefore, the improvement noted after splanchnicectomy can be directly attributed to the operation.

Improvement in life expectancy is best judged by the results in cases of malignant hypertension. In the series of Keith, Wagener and Barker¹⁰ there was a mortality of 78 per cent at the end of the first year, compared to our mortality of 36 per cent after splanchnicectomy. At the end of two years under medical treatment there was a mortality of 88 per cent, compared to a mortality of 50 per cent in those treated surgically. At the end of five years only of 146 patients treated medically was still living whereas 35 per cent were living after splanchnicectomy. Of special significance is the fact that 19 per cent of our patients with preoperative malignant hypertension are still living five to thirteen years after bilateral supradiaphragmatic splanchnicectomy.

The ability to resume a gainful occupation is of vital importance to a large number of incapacitated hypertensive patients. The frequently given advice to "slow down" and "lessen or stop working" is economically impossible for a vast number of patients. Often this advice is coupled with the phrase "stop worrying." Just how a man who needs to support his family and is told that he must stop work can help from worrying is not explained. The ability of the hypertensive patient to resume work after splanchnicectomy is one of the most gratifying results. In one of our special follow-up studies extending for a postoperative period of seven years, 55.5 per cent of patients had completely recovered from their incapacitation and had been able to return to their former occupations. Many others were so improved that they were again employed, making a total improvement from incapacitation of 81.3 per cent. The majority were able to resume work only a few weeks after the bilateral supradiaphragmatic splanchnicectomy.

Perhaps as severe a test of the efficacy of splanchnicectomy for hypertension as can be made is that of pregnancy some time after the operation. Pregnancy often appears to be the instigating factor in the development of hypertension in apparently healthy women. It is well known that pregnancy frequently accelerates the hypertensive process when

the disease is already present, so much so in some cases that a therapeutic abortion is indicated to save the mother. We have a number of patients who had had severe hypertension, in one with a systolic pressure of over 300 in whom following a bilateral supradiaphragmatic splanchnicectomy the pressure dropped to and remained normal, a subsequent pregnancy was carried to completion without incident. These pregnancies occurred one to several years after the splanchnicectomy. In none did the blood pressure rise above normal either during or after the pregnancy. All patients were free of hypertensive symptoms, and none showed any evidence of cardiac impairment or abnormal renal function.

The following case reports are given to illustrate the results obtained by bilateral supradiaphragmatic

returned with incapacitating severity, and nausea and vomiting were associated. She had noted blurring of vision for 1 month. She had been confined to bed for the previous 8 months because of the severity of the symptoms.

Physical examination revealed a severe neuroretinitis with early papilledema, flame-shaped hemorrhages and cotton-wool patches, the retinal arteries showed marked variation in caliber, with localized angiospasm and arteriovenous compression. Both lung fields were clear. The heart was not enlarged. A soft systolic murmur was heard over the precordium. Neither kidney was palpated. There was no peripheral edema. The blood pressure averaged 280/190 in both arms.

An electrocardiogram showed inverted T waves in Leads 2 and 3. Urinalysis revealed a proteinuria of 0.12 per cent, and a moderate number of red cells and casts in the sediment. The maximum specific gravity on a 38-hour concentration test was 1.033. Urea clearance was 87 per cent. A phenol-sulfonephthalein test showed 24 per cent excretion of the dye in 15 minutes. There was no anemia, and the blood serologic findings were negative.

A bilateral supradiaphragmatic splanchnicectomy was per-

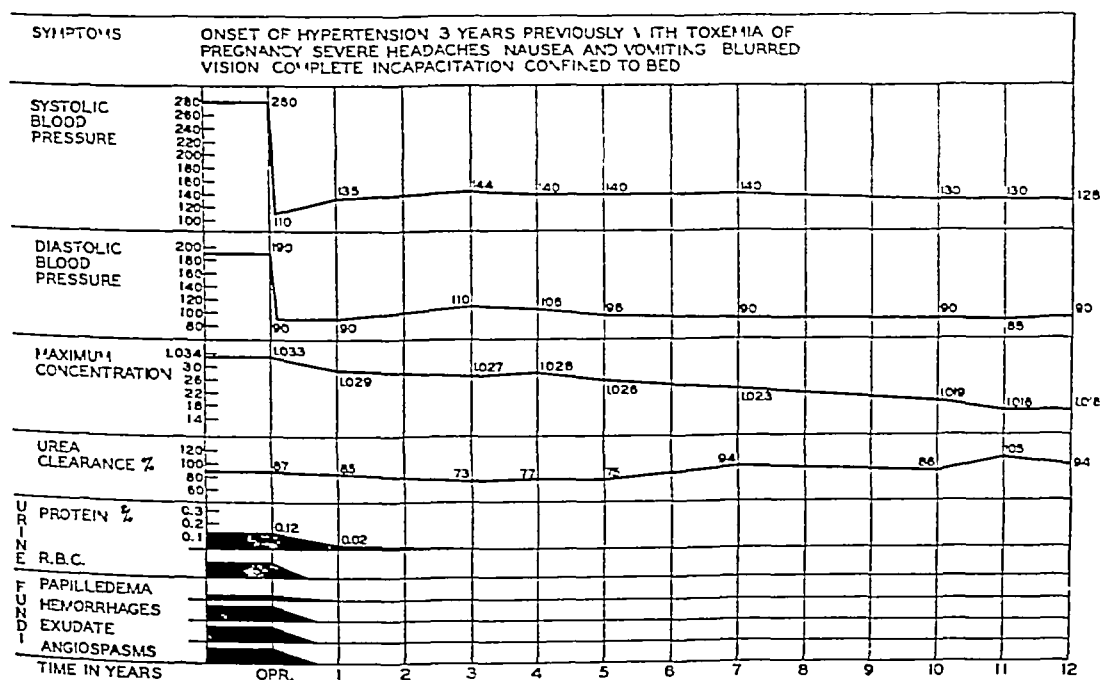

FIGURE 1 Summary of Data in Case 1

matic splanchnicectomy in many patients with severe hypertension. The first is a case of typical malignant hypertension, the second a case of hypertension with severe angina, and the third a case of pregnancy following splanchnicectomy.

Case 1 (Fig 1) Malignant hypertension. V E, a 22-year-old married woman, entered the hospital on June 16, 1934, complaining of severe headaches. An elevated blood pressure had been discovered during her first pregnancy 3 years previously, when she had complained of swollen ankles, unbearable headaches and blurred vision. The systolic blood pressure reached 250 with the toxemia of pregnancy, labor was induced during the 8th month, and a living infant was obtained. One year later the child died, and the patient immediately began to have episodes of severe precordial pain with associated numbness in the left arm. The headaches

formed on June 22. The postoperative course was uneventful and the patient was discharged in 14 days.

Follow-up study 2 months after operation disclosed a blood pressure of 145/90. The patient was completely asymptomatic. The maximum specific gravity was 1.028. The phenol-sulfonephthalein test showed 50 per cent excretion of the dye in 15 minutes. The proteinuria was 0.02 per cent. Examination of the fundus revealed that the hemorrhages and exudates had completely disappeared and that the arteries were practically normal, both optic disks were well outlined.

One year after operation the blood pressure was 135/90, and the patient was still completely asymptomatic. The ocular fundi were normal. The maximum specific gravity was 1.029, and the urea clearance was 85 per cent. The phenol-sulfonephthalein test showed 37 per cent excretion of the dye in 15 minutes. There was a proteinuria of 0.02 per cent.

Three years after operation the blood pressure was 144/110. The patient complained of a recurrence of the episodes of pre-

cordial pain. An electrocardiogram showed inverted T waves in Leads 2 and 3. A left superior cervical ganglionectomy was performed. The ocular fundi were normal. There was no proteinuria. The maximum specific gravity was 1.027, and the urea clearance was 73 per cent.

A year later the blood pressure was 140/106, and the patient was asymptomatic, with normal fundi. The specific gravity was 1.028, and the urea clearance was 77 per cent. There was no proteinuria.

Five years after operation the blood pressure was 140/96. The patient was still asymptomatic, with normal fundi. An electrocardiogram was within normal limits, with upright T waves. A teleroentgenogram revealed the heart to be of normal size. The specific gravity was 1.026, and the urea clearance was 75 per cent. There was no proteinuria.

Two years later examination revealed that the blood pressure was still 140/90, the patient was asymptomatic. There was a slight sclerosis of the retinal arterioles. There was no proteinuria. The maximum specific gravity on an 18-hour concentration test was 1.023 (previous follow-up tests had all been performed on a concentration of 36 hours). The urea clearance was 94 per cent.

Ten years after operation the blood pressure was 130/90, and the patient was asymptomatic. An electrocardiogram was normal, and the heart size was unchanged on a teleroentgenogram. The ocular fundi showed a slight sclerosis of the arterioles. The maximum specific gravity on an 18-hour concentration test was 1.019. The urea clearance was 86 per cent.

Eleven years after operation the blood pressure was 130/88, and the patient had no symptoms. There was a slight sclerosis of the retinal arterioles. An electrocardiogram was normal, as was the heart size. The maximum specific gravity on an 18-hour concentration test was 1.016, and the urea clearance was 105 per cent.

Twelve years after operation the blood pressure was 128/90, and the patient was still asymptomatic. There was a mild sclerosis of the retinal arterioles. An electrocardiogram and the heart size were normal. The maximum specific gravity was 1.016 on an 18-hour concentration test. The urea clearance was 94 per cent.

CASE 2 Hypertension with severe angina pectoris. M S, a 40-year-old housewife, entered the hospital on September 2, 1941, complaining of episodes of excruciating pain across the upper anterior chest that were consistently related to exertion and disappeared after 5 to 15 minutes of rest. She had first been discovered to have high blood pressure 10 years previously. She had had two to six episodes of severe substernal pain daily for the previous month.

Physical examination revealed a moderate sclerosis, localized angiospasm and arteriovenous nicking but no hemorrhages or papilledema. Both lung fields were clear. The heart was not enlarged, a definite presystolic gallop was heard at the apex, the aortic second sound was snapping. Neither kidney was palpated. There was no peripheral edema. The blood pressure averaged 230/150 in both arms.

An electrocardiogram revealed deeply inverted T waves in Leads 1 and 2 and in the chest leads, suggesting a recent anterior myocardial infarction. The heart size was normal on a teleroentgenogram. Urinalysis was negative. The maximum specific gravity was 1.021. The urea clearance was 68 per cent. The blood nonprotein nitrogen was 32 mg per 100 cc.

The patient continued to have at least two anginal seizures daily while at rest in bed. On September 9 the T waves were much less inverted than those in the previous electrocardiogram. The blood pressure remained at 220/140. On September 18, a protracted episode of severe substernal pain required morphine for relief. On the next day the electrocardiogram showed prominent Q waves in Leads 2 and 3 and evidences of a fresh posterior myocardial infarction. Anginal seizures continued while the patient was at rest in bed. Serial electrocardiograms showed evidences of healing of the infarct. The blood pressure remained high.

Because of the persistent anginal seizures and high blood pressure, bilateral splanchnicectomy was performed on October 17. Although two recent myocardial infarcts had occurred, the postoperative course was uneventful. The patient was discharged on November 5, she did not have a single anginal seizure following operation.

Follow-up examination 5 years after operation disclosed

complete relief from the anginal seizures, there had been no subsequent coronary occlusion. The blood pressure was 164/114. No gallop rhythm was apparent. An electrocardiogram showed prominent Q waves in Leads 2 and 3. The heart size was normal on a teleroentgenogram. The maximum specific gravity of the urine was 1.021.

CASE 3 Pregnancy following splanchnicectomy. G T, a 23-year-old woman, was admitted to the hospital on April 16, 1938. She had first learned that she had an elevated blood pressure 2 years previously, when she had consulted a physician because of occipital headaches. The headaches increased in severity and frequency until admission. There were no other complaints.

Physical examination revealed marked attenuation of the retinal arterioles and occasional localized angiospasm; there was a cotton-wool patch temporal to the disk of the left eye, both disks were well outlined. Both lung fields were entirely clear, and the heart showed nothing unusual. Neither kidney was palpated, and there was no peripheral edema. The blood pressure averaged 230/145 in both arms.

An electrocardiogram was within normal limits. A teleroentgenogram revealed a heart of normal size. Urinalysis was negative for proteinuria. The blood nonprotein nitrogen was 17.2 mg per 100 cc. The maximum specific gravity on a 38-hour concentration test was 1.023. The urea clearance was 89 per cent of normal. There was no anemia, and the blood serologic findings were negative.

Bilateral splanchnicectomy was performed on April 20. The patient was discharged on the 12th postoperative day.

Follow-up examination 2 years after operation revealed complete relief from preoperative headaches, the patient was working full time as a bookkeeper and had no complaints. The ocular fundi were normal. The blood pressure was 126/82. An electrocardiogram was within normal limits, and the heart was normal on a teleroentgenogram. The maximum specific gravity was normal at 1.026 on an 18-hour concentration test. The urea clearance was 93 per cent.

Five years after operation the patient completed a full term pregnancy, a normal infant being delivered. The blood pressure remained normal, and there was no albuminuria during the entire pregnancy.

Seven years after operation the blood pressure was 118/86, and the patient was completely asymptomatic. An electrocardiogram was normal, and the heart size normal on a teleroentgenogram. The maximum specific gravity was 1.025.

SUMMARY

The etiology of hypertension is considered, especially in its bearing on surgical treatment. A new classification of arterial hypertension is presented, based on the predominant pathologic lesion.

Bilateral supradiaphragmatic splanchnicectomy, which includes excision of the greater, lesser and least splanchnic nerves, is considered the procedure of choice. The operation has been performed at the University of Michigan Hospital on over 1500 patients. The results of studies over a postoperative period of one to twelve years are given. Significant improvement in reduction of blood pressure, improvement in ocular, renal and cardiac status, alleviation of symptoms, relief of incapacitation and probable prolongation of life are reported.

Three typical case reports or the relief afforded by bilateral splanchnicectomy are presented.

PENICILLIN IN THE TREATMENT OF GONORRHEA IN WOMEN

Results of Treatment as Reported by Twelve Co-operating Venereal-Disease Clinics in Massachusetts during 1945

GEORGE E. PERKINS, MD,* AND HAROLD N. BREWSTER, MD, MPH†

BOSTON

THE application of penicillin seems to be the outstanding advance to date in the therapy of gonorrhea, the most frequent of all venereal infections. The results of treatment in both sexes, with or without complications, are so striking that all other forms of therapy now seem antiquated. This is not to say, however, that penicillin is a "miracle drug" that relieves the physician and follow-up workers of any further responsibility once a patient has received a course of treatment.

Critical analysis of the data available shows that one may come to some tentative conclusions. There are enough failures of treatment to necessitate careful repeated follow-up examinations, which should include at least four or five cultures and smears for the gonococcus. The optimum treatment schedule has yet to be worked out, but the underlying principles seem to aim at producing penicillin blood levels high enough to accomplish the desired results over a relatively short period rather than lower blood levels for a prolonged period. The rationale of this is twofold: the goal is to develop an ambulatory treatment that can be completed at one clinic session, and experience seems to show that dosage schedules that achieve these high penicillin blood levels produce a larger percentage of satisfactory results. Because of the well known repressive action of the drug on the spirochetes of syphilis, blood serologic tests should be taken six weeks after treatment and should be repeated in three months.

This paper represents an analysis of the data collected from twelve clinics that co-operate with the Division of Venereal Diseases, Massachusetts Department of Public Health. The study includes female patients with gonorrhea who were treated with aqueous solutions of sodium penicillin and

whose cases were reported to the division on special "Penicillin Study" forms from September, 1944, to January, 1946.

Many of the numerous papers written on the use of penicillin in the treatment of gonorrhea have been reports of the results of research in this field. The data of one of the co-operating clinics in Massachusetts, which is engaged in active research, are not included in this study. We are interested in examining the results of various treatment schedules as applied by a representative group of clinicians under widely differing circumstances. It is as a picture of what penicillin may be expected to accom-

TABLE 1 Results of Penicillin Treatment of Gonorrhea in Women

plish in a representative cross section of venereal-disease clinics that this paper is presented. Studies of this kind will eventually establish a sound rationale for routine treatment schedules that are applicable on a large scale for the therapy of gonorrhea in women.

Table 1 presents a summary of the results of treatment under the various dosage schedules employed in this series. Thirty-two cases reported on the study sheets were not followed after treatment and are not included in the table. Two hundred and thirty-four courses of treatment were given to

*Director, Division of Venereal Diseases, Massachusetts Department of Public Health.

†Assistant director, Division of Venereal Diseases, Massachusetts Department of Public Health.

200 patients with either proved or suspected gonorrhea. Those treated on suspicion without any particular clinical or laboratory evidence of gonorrhea were women who had been named as sources of infection by men with gonorrhea, in most cases these were military contacts.

The largest group of patients in the series received 100,000 units of penicillin. In all but 6 of these patients, who were treated according to the schedule of 20,000 units every two hours for five injections, the results were satisfactory, a percentage of 90 (Table 2). When penicillin first became available

of this case report disclosed that the patient was treated on suspicion on June 14, 1945. On follow-up study on June 20 and July 11 smears and cultures were negative. On August 8, two months after treatment, there was a positive culture, probably owing to reinfection rather than to failure of treatment. The patient was again treated with a course of 100,000 units (20,000 units every two hours for five doses), but the culture remained positive. A third course of 50,000 units every two hours for three injections finally resulted in a cure.

There were three failures in the group of 19

TABLE 2 *Results of Treatment with 100,000 Units of Penicillin according to Interval between Injections*

No. of Injections	Two Hours Between Injections		Three Hours Between Injections		Four Hours Between Injections		Totals	
	Cures	Failures	Cures	Failures	Cures	Failures	Cures	Failures
3	3 (75%)	1 (25%)	—	1 (100%)	2 (67%)	1 (33%)	5 (62%)	3 (37%)
4	1 (100%)	—	—	—	—	—	1 (100%)	—

for distribution to the co-operating clinics, this was the schedule recommended.

Forty-one patients were treated with 150,000 units of penicillin. All of these were given 50,000 units every two hours for three doses. The results were 100 per cent satisfactory. This schedule seemed to give the best results, which is surprising in view of the fact that the 44 cases treated with 200,000 units showed failures in 4, a rate of 9 per cent.

Table 3 presents the details of the various treatment schedules employed with a total dosage of 200,000 units. Eight patients were given three

patients who received 50,000 units every two hours for four injections — a total dose of 200,000 units. Analysis of the individual case reports shows that two of these failures occurred in a patient who either was resistant to penicillin or became reinfected repeatedly, or both, the failures occurred on the second and third courses of treatment. The former may well have been caused by reinfection following the first course of treatment with 100,000 units. The patient eventually developed pelvic inflammatory disease and received a fourth course of treatment, totaling 600,000 units, in the hospital.

TABLE 3 *Results of Treatment with 200,000 Units of Penicillin according to Interval between Injections*

No. of Injections	Two Hours Between Injections		Three Hours Between Injections		Four Hours Between Injections		Totals	
	Cures	Failures	Cures	Failures	Cures	Failures	Cures	Failures
2	—	—	—	—	7 (88%)	1 (12%)	7 (87%)	1 (12%)

injections of 66,666 units each at two-hour intervals. All were cured. This standard schedule was introduced by the Department of Public Health during the latter part of 1945. The excellent results in the small group recorded sustain the judgment in recommending the change, although the group is too small as yet to have statistical significance.

Further study of Table 3 shows that there were 4 cases of failure among patients receiving 200,000 units. One of these patients received two injections of 100,000 units each, four hours apart. Analysis

Subsequently, four consecutive smears and cultures were negative. Two months after treatment she returned to the clinic with positive smears and cultures. Although she denied re-exposure, it is difficult to accept this case as one of failure in the fourth course of treatment. The third treatment failure occurred in a woman who returned with pelvic inflammatory disease a month after the course of therapy. There is nothing in the report to indicate that this case could not have been the result of reinfection rather than a failure of treatment.

A total of 14 patients received 300,000 units or more, with failure in 2 (Table 4), one of which was the doubtful failure mentioned above. The results in this small group were 86 per cent successful. If

more appears to be adequate except for the unusual case caused by a resistant strain.

Table 6 demonstrates a definite decline in the trend of curability as the duration of infection

TABLE 4 Results of Treatment with 300,000 or More Units of Penicillin according to Interval between Injections

No. of Injections	TWO HOURS BETWEEN INJECTIONS		THREE HOURS BETWEEN INJECTIONS		TOTALS

300,000 or more	6 (100%)	—	—	1 (100%)	5 (100%)	—	1 (50%)	1 (50%)	12 (86%)	2 (14%)
Totals	186 (93%)	14 (7%)	16 (73%)	6 (27%)	9 (90%)	1 (10%)	1 (50%)	1 (50%)	212 (91%)	22 (9%)

to the total dosage used. The first course of treatment gave satisfactory results in 93 per cent of cases regardless of the total dosage used. The patients receiving 100,000 units made the poorest

cases and those in which the duration of infection was unknown, the cures were 92 and 85 per cent respectively. Recent work on the mode of action of penicillin indicates that bacteria are most vulnerable to the action of penicillin during the period of greatest reproductive activity. This may explain the difference in the response of acute gonorrhea to penicillin therapy as compared with that of the chronic condition. In addition, the greater activity of the host tissues in the characteristic reaction of an acute inflammation must be considered.

Table 7 presents the interesting observation that

TABLE 6 Results of Treatment according to Duration of Infection

DURATION OF INFECTION	CURES	FAILURES
0-14 days	25 (100%)	—
15-28	30 (97%)	1 (3%)
29 or more	76 (92%)	7 (8%)
Unknown	81 (85%)	14 (15%)
Totals	212 (91%)	22 (9%)

showing, with cure in only 89 per cent. If the doubtful failure referred to above is regarded as a case of reinfection, the treatment in the groups in which 150,000 units or more were employed was 99 per cent successful.

The conclusion may be drawn from this series that 100,000 units of penicillin does not constitute an adequate dose for achieving uniformly reliable results in the treatment of gonorrhea in women. Any dosage schedule employing 150,000 units or

TABLE 7 Results of Treatment according to Complications

TYPE OF GONORRHEA	RESULT	
	CURES	FAILURES
Uncomplicated	199 (91%)	21 (9%)
Complicated	13 (93%)	1 (7%)
Totals	212 (91%)	22 (9%)

the percentage of cured cases was higher in the group with complications than in that without complications. The difference, however, is not statistically significant. In general, the patients with

complications received larger doses than those with uncomplicated gonorrhea. Table 7 shows, however, that penicillin is equally effective in the treatment of gonorrhea with or without complications.

* * *

This study was based on the tabulation of information sent in by twelve co-operating clinics in Massachusetts regarding cases of gonorrhea in

women who had been treated with varying courses of intramuscular injections of an aqueous solution of penicillin. Two hundred and thirty-four courses of treatment were given in 200 cases. The best results were obtained by the use of 150,000 units or more of penicillin divided into three equal doses spaced two hours apart.

MEDICAL PROGRESS

SYPHILIS (Concluded)

G MARSHALL CRAWFORD, M D *

BOSTON

REACTIONS TO TREATMENT

A word of caution has been given by Leifer⁵⁶ regarding the continuance of arsenotherapy in patients experiencing the reaction known as erythema of the ninth day. This is an entirely distinct disturbance from the systemic Herxheimer reaction, which occurs only after the initial dose of arsenic or, rarely, after the second injection. Erythema of the ninth day may occur any time within the first three weeks of arsenotherapy, and Leifer considers it a probable manifestation of sensitivity to arsenic. An erythematous eruption may or may not be present, but fever always occurs and there may be acute hepatitis. It was often assumed that arsenotherapy could safely be resumed from one to six months after erythema of the ninth day, depending on the severity of the reaction. Leifer reports 14 cases in which the reinstitution of arsenical treatment after erythema of the ninth day was followed by a severe parenchymatous injury in the form of jaundice and agranulocytosis, with or without nephritis. Arsenotherapy had been rather promptly resumed in all these patients, 12 of whom subsequently received an intensive course of penicillin without untoward reactions.

For a considerable period after the introduction of oxophenarsine hydrochloride (Mapharsen), it was maintained that the drug caused no serious reactions and comparatively few untoward effects of any kind. As it was more widely used, however, reports of damaging effects gradually appeared in the literature. Two more cases of acute agranulocytosis, one with coexisting toxic hepatitis, have been attributed to Mapharsen therapy for syphilis.⁵⁷ Colloido-

clastic shock has rarely been reported from the use of Mapharsen, but another report of a case of this reaction has appeared.⁵⁸

It has often been pointed out that post-arsphenamine jaundice is clinically indistinguishable from infectious hepatitis. A particularly interesting example of this problem was reported in a clinical observation of syphilitic patients treated in England during the period 1941-1944.⁵⁹ Fifty per cent of the patients studied developed jaundice, the majority on about the hundredth day after the first injection. Following routine sterilization of syringes before and after each injection, the incidence of hepatitis was reduced from 50 to 10 per cent. This indicates that post-arsphenamine jaundice was spread by contaminated syringes. It could just as easily be deduced that all the patients had infectious hepatitis of the epidemic type that was transmitted by the syringes.

An example of the dangers of massive drip arsenotherapy may be found in the report of 2 additional cases of encephalopathy.⁶⁰ The first patient received 240 mg of Mapharsen over a period of eight hours, none was given thereafter. Hepatitis and toxic encephalopathy followed. The patient died eight days later. The other patient received a total dosage of 720 mg of Mapharsen in three days. A toxic erythema developed, followed by stupor and convulsive seizures. Death occurred four days after the termination of arsenotherapy. In both cases excellent care and the best forms of treatment were used.

A systemic treatment for arsenic poisoning has appeared under the name BAL or British antilewisite (2,3-dimercaptopropanol). This compound was developed during the war as an antidote to arsenical blister gases. The compound was subse-

*Instructor in dermatology, Harvard Medical School; assistant dermatologist, Massachusetts General Hospital.

quently found to be effective also in the systemic treatment of severe arsenic poisoning. Eagle⁶¹ reported that BAL has been used in more than 200 cases in various types of arsenic poisoning with results indicating that the danger of some complications may be markedly reduced by its early administration in adequate dosage. Urinary excretion of arsenic is increased for two to four hours after therapy. The drug is injected intramuscularly in oil, 25 mg per kilogram of body weight being given at each dose. Four doses are given the first two days and decreasing amounts thereafter for twelve days. In grave complications larger amounts may be used for longer periods. Of 55 patients with hemorrhagic encephalitis, 44 recovered in one to seven days. Among 51 patients with exfoliative arsenical dermatitis, 80 per cent improved within three days and recovered almost completely in thirteen days. Ten of 11 patients with agranulocytosis showed approximately normal white-cell counts within seven days. Aplastic anemia was not affected. Post-arsphenamine jaundice was cured in only 5 of 14 patients. Gluteal abscesses or cellulitis may occur with the use of this drug.

PENICILLIN

During the past year the use of penicillin in the treatment of syphilis has been widely extended. It should be emphasized at the outset, however, that the use of this drug in the treatment of syphilis should still be regarded as experimental and that the drug should not be employed without some routine chemotherapy, in conjunction with and subsequent to the penicillin. As pointed out below, the effectiveness of penicillin for the treatment of syphilis seems to be distinctly reduced, and increased dosage schedules have been advocated. This situation is being remedied, but it serves to illustrate how much has yet to be learned about the drug.

Experimental Research

The distribution of penicillin in the body after injection is not too difficult to determine in animals, but the fate of the drug is not entirely understood.⁶² It has been shown that penicillin is widely distributed through all the tissues and organs, with the exception of the nervous system. The rate of disappearance of penicillin from the blood does not seem to be influenced by biliary obstruction in rabbits, but its effect was greatly prolonged by renal obstruction. Although the major part of administered penicillin is lost in the urine and a lesser amount in bile and saliva, there remains a portion for which the fate remains unknown.

In vitro studies have shown that the action of penicillin is far greater on organisms undergoing rapid rate of growth and with increasing temperature.⁶³ At high temperatures the drug kills organisms that are not undergoing growth, this action would

otherwise require excessively high concentrations of the drug. Heightened effectiveness under increased temperatures explains the valuable effect of penicillin combined with hyperpyrexia in the treatment of neurosyphilis, as pointed out by clinical reports cited below.

Several variants of penicillin have been isolated in crystalline form. The comparative sensitivity of numerous bacterial strains to the different types of penicillin has been worked out.⁶⁴ Penicillin G is the one that seems to have the greatest effect on *T. pallidum*,⁶⁵ as demonstrated by the accelerated disappearance of surface organisms from dark-field-positive lesions. The proportions of penicillin fractions included in various commercial penicillins vary. All are apparently effective in the treatment of gonorrhea, and each of the various fractions appears to have enough effect on *T. pallidum* to mask syphilis when used in the treatment of gonorrhea.

It is believed that the action of penicillin interferes with bacterial metabolism in the early stages of growth.⁶⁶ Spirochetes isolated from patients receiving penicillin treatment were observed to become elongated. After being repeatedly passed through mediums containing penicillin, a laboratory strain of *T. pallidum* did not appear to have developed an increased tolerance to the drug.⁶⁷ Elongation of the spirochete was observed with electron-microscope studies of these cultures, and the organisms had also lost their flagella. This lengthening of the organism seemed to indicate an inhibition of cellular division. Although spirochetes have been repeatedly demonstrated to become resistant to arsenicals if therapy is not correctly carried out, there is some question whether penicillin resistance actually occurs. It is stated that such resistance may be an inherited characteristic originating through mutation, its origin being independent of penicillin treatment.⁶⁸ If initial doses of the drug are high and it is continued vigorously until the infection has been eliminated, resistance should certainly not appear. Acquired resistance to penicillin has been produced in some organisms in vitro although the mechanism is unknown.⁶⁹ The development of penicillin resistance in man has been unimportant, but the general problem of penicillin resistance of *T. pallidum* remains unsolved. In a case report of early syphilis resistant to treatment with penicillin, 2,400,000 units were given over a period of five days.⁶⁹ The chancre did not heal, although the serologic test for syphilis became negative after several weeks. The test subsequently became positive, and secondary lesions appeared. Retreatment consisted of only 600,000 units of penicillin in conjunction with eight hours of fever therapy, the response was excellent. This seems highly questionable as actual evidence of penicillin resistance. The correct dosage and time-dose relation of penicillin therapy are not definitely established. It is known that prolongation of administration has decided advantages even with

relatively lower dosage. The short period (five days) during which treatment was given could thus be the explanation for failure in the case reported. In vivo studies suggest that the maintenance of the minimal inhibitory concentration will result in remission of the syphilitic disease.⁶⁸ The minimal effective blood serum level of penicillin is not yet established, but it has been assumed that a serum level of 0.078 units per cubic centimeter must be maintained. Relapse should be prevented by a sufficiently prolonged period of maintenance of effective serum levels of penicillin. Higher concentrations apparently serve no useful purpose. Experimental work of this type backs up clinical experience of the value of prolongation of the duration of treatment.

Methods of Administration

Attempts to provide more prolonged effective blood levels of penicillin are being continued, but no outstanding advance has been reported during the past year. Slower absorption of penicillin from the site of injection by its incorporation in oil and wax is currently undergoing wide usage. Methods of slowing the rate of excretion have not proved satisfactory for routine employment. For all acute infections of any severity and for syphilis, the oil and wax vehicle is so far considered inferior to more rapidly diffusible diluents.

The oral administration of penicillin continues to receive a good deal of attention. Four to five times the intramuscular dose must be administered orally to obtain serum levels of comparative effectiveness. It has been shown that oral therapy with penicillin is effective in gonorrhea⁷⁰ and in other infections in which low dosages of parenteral penicillin have proved adequate.⁷¹⁻⁷⁴ So far as is now known, it should be unmistakably stressed that the oral administration of penicillin in the treatment of syphilis has not yet been shown to be satisfactory.

The so-called "Romansky formula"^{75, 76} for penicillin in beeswax and peanut oil has been shown to maintain effective blood levels of penicillin for about twenty-four hours in some patients, it continues to be excreted in the urine for approximately three days. This method of penicillin therapy is reported as adequate for most situations but not for overwhelming infections. An average dose of 300,000 units is required. Subcutaneous administration of this preparation has also been employed with satisfactory results.⁷⁷ In the treatment of syphilis several daily doses rather than a single injection seem to be required for satisfactory effect.⁷⁸ Aluminum and penicillin mixtures have also been used,⁷⁹⁻⁸¹ with results that deserve continued experimentation. Like the oral administration of penicillin, however, oil and wax mixtures cannot yet be recommended for use in the treatment of syphilis. No satisfactory outpatient plan of penicillin therapy for this disease has so far been established.

Penicillin in Early Syphilis

The danger of masking early syphilis during the treatment of gonorrhea with penicillin is of considerable magnitude. Since the advent of the sulfonamide drugs and penicillin, it is simpler than ever before for the general practitioner to treat gonorrhea. The symptoms of this disease may develop and the treatment may be completed with apparent cure several days before the primary lesion of syphilis normally appears. The comparatively small amount of penicillin necessary to cure gonorrhea is sufficient to abort temporarily the lesions of early syphilis for a considerable period. I have observed a case of early syphilis with a history of penicillin therapy for gonorrhea fourteen months prior to the appearance of clinical early syphilis. Exposure to venereal infection of any sort during the intervening period was consistently denied. Continued reports of this phenomenon have appeared in print, and one cannot be too careful in following patients with gonorrhea for some months after treatment.

Experimental work with small doses of penicillin comparable to those used in the treatment of gonorrhea has been carried out in rabbits inoculated with syphilis. It was the opinion of Magnuson and Eagle,⁸² who did this work, that an actual abortion of the infection, rather than suppression of the development of the primary lesion, took place. Many of the delayed lesions were so small that comparable lesions in man might not be detected, an apparently asymptomatic condition being thus produced. The authors believed that patients with gonorrhea should be followed clinically and serologically for four months or longer, this certainly seems to be a minimum period of observation. A sufficient number of case reports illustrating the danger of suppressing syphilis during gonorrhea therapy⁸³⁻⁸⁷ are available to indicate that this may become a public-health problem. Some authors believe that when there is evidence or suspicion of coexisting syphilis, penicillin therapy for gonorrhea should be withheld until a definite diagnosis of syphilis can be established or eliminated.

The frequency with which penicillin therapy for syphilis is accompanied by a Herxheimer reaction makes it possible to utilize this phenomenon as a possible clue to syphilis when penicillin is used in the treatment of other infections. It has been stated that the occurrence of chills or fever accompanying penicillin therapy for gonorrhea not obviously complicated by syphilis is strong presumptive evidence of the coexistence of syphilis.⁸⁸ There are exceptions to the rule, but it is at least a safe precaution to subject a patient displaying a febrile reaction to closer than usual scrutiny for a period of several months following penicillin treatment for gonorrhea.

Sufficient data are beginning to accumulate regarding the treatment of early syphilis with penicillin to establish a more adequate appraisal of the dosage required to achieve satisfactory results. Only comparatively immediate effects can be deduced, however, until the patients have been followed for periods up to at least twenty years. Pillsbury^{89, 90} reports follow-up examinations of 792 patients, six months or more after treatment with penicillin as given by the routine Army schedule. Tables are presented showing the incidence of relapse, the types of lesions, the results of serologic tests at various intervals, as well as a comparison of these penicillin-treated patients with the groups receiving prolonged courses of arsenicals and heavy metal, and the twenty-day intensive arsenobismuth plans of therapy. Pillsbury found that although penicillin therapy in early syphilis exhibits few toxic effects and the patient is rendered promptly noninfectious, with a low incidence of infectious relapses, this treatment compares unfavorably with arsenobismuth therapy in its achievement and maintenance of seronegativity. With a prompt diagnosis of syphilis the effectiveness of a single course of penicillin treatment is extremely high, 98.18 per cent of seronegative primary syphilis cases and 87.32 per cent of seropositive primary syphilis cases were considered satisfactory cures. Of the patients with secondary syphilis only 72.07 per cent became seronegative. Spinal-fluid examinations showed the incidence of progression to neurosyphilis to be extremely low as compared with those following arsphenamine and heavy-metal therapy. Penicillin, as a single therapeutic agent against syphilis, although it is remarkably effective, appears to deserve the assistance of some metallic therapy. Schoch and Alexander⁹¹ advocate the concurrent use of penicillin and Mapharsen. They have given 2,400,000 units of penicillin over a period of seven and a half days in conjunction with 40 mg of Mapharsen daily for eight days, an alternate program includes the same amount of penicillin with bismuth salicylate 0.2 gm in oil on alternate days for five injections. The results with both combinations show a definitely higher cure rate than with penicillin alone. These authors also advocate coincidental penicillin treatment of sexual partners, regardless of proof of infection, to prevent reinfections of the so-called "ping-pong type." Penicillin schedules employed by the United States Navy⁹² require 2,400,000 units for primary syphilis, whereas patients with secondary and latent cases receive 4,000,000 units. Therapeutic results were comparable to those of the preceding reports.⁹³ Others are in agreement that a dosage of 2,400,000 units is the minimal satisfactory amount of penicillin for early syphilis and that varying quantities of chemotherapy in conjunction with or subsequent to the penicillin are advisable.⁹⁴⁻¹⁰¹ There has been experimental work in animals to verify this opinion.¹⁰² The use of penicillin com-

bined with fever therapy in the treatment of early syphilis has also been advocated.¹⁰³ Small groups of patients were treated with varying amounts of penicillin and concurrent hyperpyrexia. The results showed that smaller amounts of penicillin were necessary to cure early syphilis when administered in conjunction with fever therapy. Too little has been done with this to warrant definitive statements regarding dosage. Appraisal of these reports on the penicillin treatment of early syphilis will clearly indicate that dosage schedules, time-dose relations and combined-therapy methods require a great deal of further study before optimal programs are worked out.

Penicillin during Pregnancy

It has been demonstrated by a number of observers that penicillin passes through the placenta in sufficient amounts to provide an adequate bacteriostatic level in the fetal circulation.¹⁰⁴⁻¹⁰⁶ The obvious inference is that penicillin should eradicate syphilitic infections in both the mother and fetus. Since transmission to the fetus has been shown as early as the tenth week of gestation,¹⁰⁷ satisfactory treatment of prenatal syphilis early in pregnancy should be readily accomplished. There are clinical reports indicating that this is a safe and effective procedure. The penicillin treatment of groups of pregnant syphilitic women in Baltimore and Philadelphia clinics exhibited highly successful results in the prevention of congenital syphilis.^{108, 109} It was found that reversal of the mother's blood serologic tests to negativity was not necessary to produce a normal infant. Many infants who were born with positive serologic reactions became negative within a month's time. All the mothers had early syphilis, some were treated as late as the thirty-second week in pregnancy. A reduced initial penicillin dosage for the first forty-eight hours is advocated to avoid possible reactions. The Baltimore group believes that any suggestion that penicillin has abortifacient effects is unwarranted. It is advisable to follow the pregnant woman clinically and with repeated titrated serologic tests at least once a month until delivery and at appropriate intervals thereafter. Retreatment with penicillin should be given to the mother during pregnancy if there is evidence of clinical or serologic relapse or if the original maternal serologic titer does not significantly decline within three months after treatment. It is believed that, pending further information, a pregnant syphilitic woman whose infection has apparently been previously treated successfully with penicillin should be retreated with penicillin in each succeeding pregnancy.

Congenital Syphilis

Although the earliest reports regarding the penicillin treatment of congenital syphilis were not so optimistic as those in other forms of the disease, later publications are somewhat more encouraging.

The most satisfactory results have been obtained in cases of early congenital syphilis with manifest symptoms^{110, 111}. In patients with asymptomatic early congenital syphilis there is no clinical guide, but a gradual decrease in the titer of the blood may be observed in most cases. In late congenital syphilis, especially among patients with interstitial keratitis and neurosyphilis, clinical and laboratory findings indicate a much poorer response¹¹⁰. The penicillin treatment of syphilis in infants and children, either the congenital or the acquired disease, leaves much to be desired¹¹². Dosage schedules so far recommended vary from 20,000 units per kilogram of body weight (divided into sixty doses)¹¹³ to as high as three times that amount^{110, 114}. Periods of administration of from seven and a half to twenty days have been advocated.

Late Syphilis

The predominant attention to the use of penicillin in syphilis has been directed toward early infections. A few reports regarding management of the later stages of the disease are becoming available. A small group of patients with benign late gummatous syphilis were treated and followed for an average period of about fourteen months¹¹⁵. Cutaneous, mucocutaneous and mucous-membrane gummas, osseous lesions and hepatic gummas were included. The minimal dosage was 2,000,000 units, and the maximum was 4,000,000 units in some cases. There was a relatively rapid symptomatic response in all patients, although the objective findings in the hepatic cases were slower to improve. There was also a case of incidental gummatous keratitis that responded satisfactorily.

Syphilitic Nephrosis

One of the less frequent but more spectacular symptoms of syphilis is acute syphilitic nephrosis. The patients develop marked and widespread edema, with gross proteinuria and critically reduced plasma proteins. To establish the diagnosis, syphilis must be proved, with the absence of other urinary findings and lack of evidence of any of the usual causes of nephrosis. Two cases of rather dramatic response of acute syphilitic nephrosis to treatment with penicillin were recently reported^{116, 117}.

Ocular Syphilis

Syphilis can affect the eye in many ways, and the treatment in these cases requires considerable care. The eye is an organ in which the occurrence of a Herxheimer reaction may cause extremely unfortunate destruction. In a group of 17 patients with iritis associated with the lesions of early syphilis who were treated with penicillin alone, the incidence of Herxheimer reactions was kept down by properly reduced initial dosage¹¹⁸. Treatment was started with 5000 to 20,000 units, the dosage being gradually

increased to 50,000 to 60,000 units, with satisfactory beneficial effects.

Cardiovascular Syphilis

There has been considerable hesitancy on the part of cardiologists regarding the use of penicillin in cardiovascular syphilis¹¹⁹. This uncertainty is not shared by most syphilologists, although more care is exerted in the plan of treatment employed. It is a well known fact that Herxheimer reactions can be prevented by steadily increasing doses of any drug used in the treatment of syphilis. Even when initial therapy is low in dosage, a repetition of the same small amount may be followed by a Herxheimer reaction. It is quite likely that the pursuance of this policy would be accompanied by extremely few cases of reaction to penicillin in cardiovascular syphilis.

Neurosyphilis

There were for a time conflicting reports regarding the penetration of penicillin into the spinal fluid, regardless of means of administration other than intrathecal. Further reports indicate that systemic administration of penicillin in doses generally used will not consistently produce measurable levels of penicillin in the spinal fluid¹²⁰. There is apparently a somewhat greater tendency for the drug to reach the subarachnoid space in the presence of meningitis. Therapeutic spinal-fluid levels of penicillin are not attained unless blood serum levels much higher than the usual minimal effective quotient are maintained for periods of twelve hours or more. Massive doses of penicillin by continuous intravenous drip were followed by the appearance of penicillin in significant amounts in the spinal fluid of a large percentage of patients¹²¹. The use of fever in conjunction with intramuscular penicillin does not appear to affect the concentration of penicillin reaching the spinal fluid¹²². The penetration of penicillin through the meninges seems to be irregular and unpredictable in meningeal infections of all types¹²³.

Nevertheless, there are ample reports substantiating the value of penicillin in the treatment of various forms of neurosyphilis. Again, some of the best results have been obtained when the drug is used in conjunction with other forms of therapy. Large and small groups of cases, including all types of neurosyphilis, have shown encouraging results, except in the end stages of general paresis^{92, 124-133}. Smaller amounts of penicillin and shorter courses of fever therapy have been found necessary when given concurrently or in succession than when either was used alone. The use of this combination in primary optic atrophy is quite encouraging. It is the opinion of most observers that all forms of parenchymatous neurosyphilis require fever therapy as well as penicillin. Some state that improvement with penicillin appears sooner than with other methods, it is fre-

quently manifested within a few months, rather than as long as a year or more after malaria therapy. The most striking effects of penicillin are exerted on the spinal-fluid formula, where some improvement may be noted by the time therapy is terminated. There is no correlation between spinal-fluid response and the effect on blood serologic findings. The symptomatic phases of *tabes dorsalis* respond to penicillin therapy to an encouraging extent, with the exception of Charcot joints. Whereas penicillin alone is apparently no better than malaria alone and probably is not so effective, the two together appear to enhance each other's effect. Dosage schedules of penicillin for neurosyphilis have varied widely, from 4,000,000 to 10,000,000 units being advocated. Some observers consider repeated courses of penicillin at intervals of a few months more beneficial, but in general the higher dosage programs with prolongation of the time of administration of a single course are preferred. There is fairly general agreement that penicillin alone is not capable of controlling the graver forms of parenchymatous neurosyphilis.

The intrathecal administration of penicillin continues to receive some attention. When introduced in this manner the drug is known to remain in the spinal fluid for periods of twenty-four to seventy-two hours. The injections are given by the Swift-Ellis technic. Treatments may be given daily or as much as a week apart, the suggested doses are at great variance.¹³⁴⁻¹³⁶ The number of treatments that can or should be given has not yet been determined. Intrathecal penicillin may be used in cases in which malaria therapy is contraindicated, and the results are encouraging. Combined intraspinal and intramuscular penicillin has also been advocated. This method is certainly not yet adaptable for general use, since some serious reactions have occurred.

Reactions to Penicillin

In general, it may still be said that reactions to penicillin therapy have been fewer and milder than those with any form of treatment for syphilis heretofore devised. Nevertheless, as with practically every new drug of any sort, an increasing number and variety of side actions have been observed.

The Herxheimer reaction is perhaps the most frequent and is of little importance in early syphilis, but may be dangerous in several forms of visceral syphilis. This may be avoided by starting with small doses (as little as 1000 units) and gradually increasing to the optimum dose.

Urticaria has been observed rather frequently and is, as a rule, merely a troublesome affair. Angioneurotic edema is less frequent but may even prove fatal.¹³⁷ Fungous infections are not infrequently aggravated,^{92, 138, 139} and the so-called "id eruptions" may appear, either epidermophytids or bacterids.¹⁴⁰ It is believed by some investigators that a previous acute fungous infection may cause increased re-

activity to penicillin.¹⁴¹⁻¹⁴³ The tissue primarily affected in most penicillin reactions is reported to be the blood vessels rather than the epidermis. Purpuric eruptions and severe arthralgia have occurred.¹³⁹ A syndrome similar to serum sickness has been observed on a number of occasions.¹⁴¹⁻¹⁴⁶ Eruptions typical of toxic erythema multiforme have been described, as have those characteristic of erythema nodosum.¹⁴⁵ Aggravation of a considerable variety of pre-existing skin diseases has been reported.¹³⁸ Contact dermatitis is not infrequently observed,¹⁴⁶⁻¹⁵⁷ including involvement of the eyelids. This is of the greatest significance among medical personnel and laboratory workers handling penicillin solutions over long periods.

I have observed a case of an extremely severe reaction to penicillin that nearly caused death. So far as could be ascertained from the preceding physicians, the patient had received no other drug known to be capable of causing dermatitis. After three days of penicillin therapy for an upper respiratory infection, the patient developed a toxic eruption similar to erythema multiforme. Within twenty-four hours it became generalized, and mucous-membrane lesions interfered with the taking of nourishment. On the third day there were dysphagia and nausea, indicating probable lesions of the gastrointestinal tract. Generalized edema and exfoliative dermatitis quickly followed. Six weeks of hospitalization were required for recovery.

Decreased Potency

Unfortunate publicity by the lay press gave rise to doubts in the mind of the general public and many physicians regarding the efficacy of penicillin during the past year. There were some grossly inaccurate and irresponsible statements in the newspapers before any official scientific report could be prepared and released. It became known to those most closely following penicillin research toward the middle of 1944 that the treatment of syphilis with this drug was somewhat less satisfactory. Many wheels were immediately set turning to decipher the cause, and eventually it was found that the increased purity of commercial penicillin was at fault. There are several penicillins, and penicillin K has been shown to be of little or no value in the treatment of syphilis, as well as certain other infections, because it is too rapidly destroyed in the body.¹⁵³ As commercially supplied by some manufacturers in a purer form, far larger amounts of penicillin K were included, the amount was not large enough to cause a serious reduction in the value of penicillin in the treatment of syphilis and need not have caused alarm. Progressively less penicillin K is now found in commercial preparations, and the situation has meanwhile been controlled by the mere increase of penicillin dosage in the treatment of syphilis. An official statement on the use of penicillin in syphilis was finally released

after the appearance of newspaper publicity.¹⁵⁹ Subsequently, a full report was published giving suggestions regarding the use of the drug in the treatment of syphilis.^{160, 161}

Although the best method for the employment of penicillin in the treatment of syphilis cannot be arbitrarily stated, certain minimum suggestions for treatment were given. For seronegative primary syphilis not less than 3,600,000 units was advised, and for seropositive primary and early secondary syphilis, not less than 5,400,000 units seemed imperative. In cases of relapse, including possible reinfection, after previous treatment, the course of 5,400,000 units should be repeated, followed by 360 mg of Mapharsen or an analogous drug given twice to three times weekly in six individual intravenous injections of 60 mg each, in addition to 1200 mg of bismuth subsalicylate given twice weekly in six individual intramuscular injections of 0.2 gm each. For a second relapse of early syphilis after previous penicillin treatment the patient should be transferred from penicillin entirely and placed on intensive metal therapy. Further recommendations were given for the management of various other phases of syphilis and its complications. The administration of penicillin in oil and wax for the treatment of syphilis has not been worked out sufficiently to be considered satisfactory. Under no circumstances should penicillin in its present available form be administered orally for the treatment of syphilis. The changing character of commercial penicillin and the consequent alteration in plans of administration should serve to emphasize that penicillin therapy for syphilis is still incompletely evaluated. It will take some years of further work and careful follow-up study before the actual status of this drug in the management of syphilis can be finally determined.

SUMMARY

The release of several million young men from military duty places a greater burden than ever on public-health facilities in the prevention of venereal disease. The responsibility is squarely back on the shoulders of every state and local board of health, although the United States Public Health Service is still carrying on large-scale control measures. Education of the public continues to be of inestimable value in this respect.

The state of Alabama is continuing its legally required mass blood-testing program with extremely satisfactory results.

Studies of mortality on a nationwide basis indicate that the death rate from syphilis is slowly but steadily decreasing. Figures indicate that untreated syphilis may reduce the span of life by as much as 20 per cent. Properly treated syphilis, however, will shorten the life expectancy only about half as much.

Serologic problems in the diagnosis of syphilis and false-positive blood tests continue to be a

stumbling block. The question of reinfection of the human being with *Treponema pallidum* may have been overemphasized in the face of rapid cures by recent methods of intensive therapy and by the use of penicillin. Advocates of any form of treatment may be too reluctant to admit the likelihood of relapse.

A most instructive ten-year study of late syphilis has finally appeared, showing conclusively that adequate antisyphilitic treatment reduces the hazard of late serious complications to a minimum even though the blood serologic reactions may not reverse to negative.

A survey of a large group of patients undergoing lumbar punctures suggests that the emotional reaction of the patient may be of great importance in the incidence of post-puncture headaches.

The treatment of syphilis seems to swing ever farther away from the massive dose five-day schedules. Multiple injection programs over short periods have proved much safer. One of the most important advances in combating treatment reactions is the use of BAL (2,3-dimercaptopropanol). This drug has been found to be remarkably effective in the systemic treatment of several forms of severe arsenic poisoning. Urinary excretion of arsenic is strikingly increased, and side actions from this drug are comparatively few. Such complications as hemorrhagic encephalitis, exfoliative dermatitis, agranulocytosis and post-arsphenamine jaundice have shown most gratifying response.

The greatest emphasis in the treatment of syphilis will continue to lie in the use of penicillin. Experimental studies with the various penicillins, regarding methods of administration, effects on specific organisms, the possible development of resistance and so forth continue. As yet, the use of the highly soluble forms of penicillin, with frequent injections over periods of some days, is the only acceptable method of administration. Less frequent administration in oil and wax may prove to be suitable. The combination of penicillin with arsenotherapy and the concurrent use of penicillin with hyperpyrexia seem to hold the greatest promise. One pitfall is the possibility of masking early syphilis with the use of small amounts of penicillin for the treatment of gonorrhea, many cases have been reported. The greatest volume of penicillin therapy has been given in early syphilis, but as yet an entirely satisfactory schedule has not been worked out. Its use in other forms of the disease lags somewhat but is also encouraging. Reactions to penicillin have increased in number and variety but have rarely been grave.

Perhaps the best example of the fact that penicillin therapy for syphilis should still be considered largely experimental is the altered potency of this drug. A number of commercial preparations have been found to contain large proportions of a type of penicillin that is comparatively ineffective against syphilis. This has necessitated marked increases in

the amount of the drug necessary to provide satisfactory response. It can hardly be said that a great deal more is known about the effectiveness or long-term value of penicillin at present than a year ago. It must again be stated that much more work and many more years will elapse before satisfactory programs are established.

CASE 33081

PRESENTATION OF CASE

A fourteen-month-old boy was brought to the hospital in a semistuporous condition.

The patient had been born in the eighth month of pregnancy after premature spontaneous rupture of the fetal membranes. The mother was well. The father, an Army veteran, had had malaria and suffered from hay fever. No difficulties attended the delivery, and the infant was subsequently well until the onset of the present illness. He talked at one year and before admission was walking with help. Three months before admission, a nystagmus was noted. One month later the appetite began to fail, and in the two months before admission there was a weight loss of 2 pounds. Immunizations against diphtheria, pertussis and tetanus were carried out during the same period. In the month before admission a habit of pounding the fists on the head was noted, but in general the child was not thought to be sick until a week before admission, when a moderate upper respiratory infection with laryngitis developed. This cleared without special treatment, and the patient was well until the day of admission. At breakfast he seemed feverish and restless. The mother administered an enema, the return being gray green. Afterward the patient screamed continuously for two hours, doubled up, closed his eyes and put back his head. The temperature was found to be elevated. He vomited four times and could not retain fluid.

Physical examination showed the skin and scleras to be faintly yellow. The head measured 47 cm., and the chest 45 cm. in circumference. There was a slight left lateral nystagmus, as well as tonic deviation of the eyes to the left. The pupils were equal and reacted to light. The fundi were normal, as were the nose and ears. Slight weakness of the right lower facial muscles was observed. The pharynx was slightly reddened. The neck resisted flexion. The heart, lungs and abdomen were normal. The patient moved all extremities freely. The limb reflexes were normal, but the abdominal reflexes were absent.

The temperature was 105°F, the pulse 190 and the respirations 34.

Examination of the blood disclosed a red-cell count of 4,200,000 and a white-cell count of 17,000, with 62 per cent neutrophils.

No urine was obtained until the second day after glucose had been given intravenously. Then only a small amount was obtained, which showed an orange sugar reaction and a +++ test for acetone. The initial lumbar puncture yielded several cubic centimeters of bloody fluid that was slightly, but definitely, xanthochromic after centrifugation. The pressure was increased, but the patient was sitting and crying. Microscopically, the fluid contained innumerable red cells, as well as 60 lymphocytes per cubic millimeter and no polymorphonuclear cells. No organisms were found. The Pandy test was strongly positive. The protein was 440 mg., and the sugar 76 mg. per 100 cc. and the chloride 126 milliequiv. per liter.

X-ray examination of the skull was negative. Abundant colonies of alpha-hemolytic streptococci were cultured from the throat. There was no growth from the spinal fluid on chocolate agar. The blood-agar plate was contaminated.

The immediate treatment consisted of intravenous fluids and intramuscular penicillin. The temperature and pulse had fallen to normal by the second day, but soon began to rise again. Only 3 drops of pink fluid under little pressure were obtained on two additional lumbar taps. The fluid contained 80,000 red cells, of which 20 per cent were crenated, and 60 lymphocytes per cubic millimeter. On the afternoon of the same day the neurologic findings were somewhat altered. The right facial weakness was absent, and the eyes were held straight, deviating only occasionally to the right and left. The plantar reflexes were extensor. The patient was restless and irritable. Three hours later he was deeply comatose, with gasping respirations at a rate of 16 per minute. The reflexes were depressed. There was an erythematous macular rash on the cheeks and trunk that did not fade on pressure. On the same evening, he stopped breathing while being prepared for operation. The air passages were suctioned, and manual oxygen insufflation through an intratracheal tube was carried out. An operation was then performed.

DIFFERENTIAL DIAGNOSIS

DR. JOST J. MICHELSEN: I think it will be agreed that there is little information in this record to help us in arriving at a satisfactory conclusion. Of course, a neurologic diagnosis in this age group is always difficult, since the history and the results of examination are, as a rule, incomplete. In the case under discussion information is even more scanty than in the average.

It is almost certain that the patient had some sort of intracranial disease. We might even go a step farther and say that there was probably increased

intracranial pressure Apparently, there was terminal respiratory failure, which is a common occurrence in cases with increased intracranial pressure Before I continue with the discussion, however, I should like to ask two questions, How should one interpret the erythematous macular rash on the cheeks and trunk during the terminal phase of the disease, and what is the significance of the sugar and acetone found in the urine?

DR ALLAN M BUTLER I do not know the significance of the rash I did not see it So far as the sugar in the urine is concerned, according to the abstract the first specimen was obtained after intravenous glucose was started

A PHYSICIAN It was obtained after the intravenous drip had been administered for twenty-four hours

DR MICHELSEN Is it usual for acetone to be present with such intravenous glucose?

DR BUTLER If the urine was obtained after twenty-four hours of intravenous glucose and the patient did not have diabetes, the acetonuria was unusual

DR MICHELSEN Let us scrutinize the data that might help to determine the type of lesion that this patient had We are told that there was rigidity of the neck As is well known, rigidity of the neck is most frequent with intracranial infections, particularly with those of the subarachnoid and subdural spaces, it also occurs as a manifestation of meningeal irritation following hemorrhage into the subarachnoid and subdural spaces Less often, it is found in association with tumors that occupy the posterior fossa or as a result of herniation of the cerebellar tonsils into the foramen magnum There is no evidence that the patient had intracranial sepsis, notwithstanding the fact that a few days prior to the onset of the more recent manifestations there was an upper respiratory infection Offhand, there is also no evidence that the child had a brain tumor This leaves, as the only alternative, an intracranial hemorrhage The cerebrospinal-fluid findings suggest that this hemorrhage occurred into either the subarachnoid space or the ventricular system, or perhaps both The question then arises, How much significance should be attributed to the cerebrospinal-fluid findings of 80,000 red cells and 60 lymphocytes per cubic millimeter? There seems to be something wrong in this observation Considering the high white-cell count in the blood—17,000, with 62 per cent neutrophils—and the number of red cells in the spinal fluid, one would expect about 200 polymorphonuclears in the spinal fluid Apparently, only red cells and lymphocytes were found The differential count could not have been correct It is said that the fluid after the initial lumbar puncture, which contained a large number of red cells, was definitely xanthochromic after centrifugation I should expect any grossly bloody cerebrospinal fluid to show discoloration of the supernatant fluid

after centrifugation, since, of course, it is mixed with serum I should also assume that this lumbar puncture was difficult, since a routine lumbar puncture is not performed in the sitting position As a rule, if possible, we use three test tubes to determine the source of blood in the cerebrospinal fluid If the cerebrospinal fluid is equally bloody in all three, we are compelled to assume that the bleeding has occurred prior to the lumbar puncture, most probably in the intracranial cavity If, however, the appearance of the fluid changes and the second and third fluid portion look clearer and contain less blood than the first one, it is likely that the blood originated from the site of the puncture Is there any information regarding this point in the hospital record?

A PHYSICIAN No, only one tube was used, since the fluid came out as if under pressure

DR MICHELSEN There was actually increased pressure, then

Let us assume that an intracranial hemorrhage had occurred and discuss some of the causes of such an event A hemorrhage may be due to trauma, a congenital aneurysm, an angiomatous tumor and disease of the cerebral arteries following infections, including bacterial endocarditis and hemorrhagic diathesis There is nothing to indicate that this child had received a head injury or that there was a hemorrhagic diathesis The spinal-fluid picture was hardly consistent with that of bacterial endocarditis Furthermore, the heart was normal

Congenital aneurysm is one of the most frequent lesions producing subarachnoid hemorrhage with symptoms of meningeal irritation, changes of awareness, fever, glycosuria and certain focal signs, such as were present in this case I have never seen a subarachnoid hemorrhage from a congenital aneurysm in an infant, however, and I did not find any case reported in the literature Our choice, then, seems to be limited to an angiomatous malformation or arterial disease as a result of infection This child had an infection a week before admission Throat cultures showed abundant alpha-hemolytic streptococci Infections such as diphtheria, influenza, scarlet fever and pneumonia can produce destructive changes in the smooth muscle and elastic tissue of the media of the arteries, resulting in necrosis and subsequent hemorrhage Since I have no personal experience with rare types of arterial hemorrhage, I consulted various books and found that these changes reach their maximum on the eighteenth day or later If that observation is correct, the much shorter interval between infection and hemorrhage in the case under discussion precludes this possibility Moreover, the onset of the disease probably antedated the upper respiratory infection by several months Nystagmus was noted at the age of eleven months, in addition to a habit of pounding the fists against the head, presumably indicating that the child had headaches

Was the nystagmus a manifestation of the local effect of the disease, or was it a symptom of a minor hemorrhage at that time? This question is difficult to answer. My guess is that the nystagmus was due to involvement of certain structures in the posterior fossa rather than to a minor hemorrhage. This leads us to the problem of localization of the lesion. Do the other neurologic findings point to a lesion in the posterior fossa? They are at least consistent with it. There was weakness of the right lower facial nerve which may have been due to brain-stem disease. The bilateral Babinski signs do not help in the localization at all.

In summary, I might say that subarachnoid hemorrhage from a congenital aneurysm is quite unlikely, that I hesitate to consider the possibility of a hemorrhage as the result of postinflammatory arterial changes and that the possibility of an angioma is a fairly good one, if the blood in the cerebrospinal fluid was not due to a bloody tap. Without the cerebrospinal-fluid findings one thinks of a tumor, whose type I cannot predict. As to the localization, all the evidence given to us points to a lesion in the posterior fossa. Needless to say, I expect to be wrong on all counts.

DR BUTLER I am astonished that you did not ask to see the x-ray films.

DR MICHELSEN I did not ask because they were said to be negative.

DR BUTLER Do you accept that as correct?

DR MICHELSEN I trust the X-ray Department.

DR BUTLER I should like to see the films. The reason I ask is that it is hard for me to believe that there was no separation of the sutures. Do you think that there was, Dr Schatzki?

DR RICHARD SCHATZKI No.

DR BUTLER This was a fourteen-month-old baby. You are sure that these sutures are no wider than they should be?

DR SCHATZKI I may be wrong, but I do not care to qualify the statement.

DR BUTLER The abstract of the case fails to indicate the severe state of collapse. The doctors who took care of the patient were handicapped in carrying out diagnostic and surgical procedures because they thought the child was going to die at any moment. The first neurologic note states "He will have to be studied as rapidly as possible consistent with his condition. I agree that the extreme dehydration must be treated now." Another note by the neurosurgeon reads "The child was taken to the operating room at 5:35 p.m., and while the head was being shaved, respirations ceased. The air passages were cleared. The child was intubated, and the above procedure was done with oxygen insufflation" — the "above procedure" being bilateral burr holes. One must be careful about performing a lumbar puncture in a patient like this. I question the advisability of doing a lumbar puncture in the sitting position, unless there is some excellent reason

for doing so, the reclining position appears preferable. When a lumbar puncture is performed on a child in whom one suspects increased intracranial pressure, the fluid should be removed with the greatest of care and only the minimal amount necessary for diagnostic procedures withdrawn. If evidence of increased intracranial pressure has been obtained by burr holes, it seems to me that the pressure should be reduced by ventricular tap. If desired, ventriculograms can then be obtained. Pneumoencephalograms in such patients with increased intracranial pressure are to be avoided as unduly dangerous. In this case, however, we shall learn from the pathologist's findings that there was not much that could have been done.

DR F. DENNETTE ADAMS How do you account for the high white-cell count and fever?

DR BUTLER The patient may have had some infection. The degree of dehydration alone, however, could have accounted for the elevation of the white-cell count. The dehydration, in addition to the intracranial disease, may have caused the elevated temperature.

CLINICAL DIAGNOSIS

Subdural hematoma?

DR MICHELSEN'S DIAGNOSIS

Expanding lesion in posterior fossa, type undetermined.

ANATOMICAL DIAGNOSIS

Brain tumor, probably oligodendroglioma

PATHOLOGICAL DISCUSSION

DR CHARLES S. KUBIE I agree with Dr. Michelsen that this was an unusually difficult case. I think that he did very well with the data available.

There was a soft tumor, almost gelatinous in consistency, 6 cm. in diameter, above the optic chiasm. It extended forward along the medial portions of the orbital surfaces of the frontal lobes, backward to the interpeduncular space and upward into the hypothalamus and third ventricle. The optic chiasm, olfactory lobes, tuber cinereum, a large part of the hypothalamus and the corticospinal tracts were invaded by the tumor. I should have expected serious impairment of vision. In the upper part of the tumor there was a small hemorrhage, communicating with the third ventricle, which unquestionably was the source of the blood in the spinal fluid.

We have had several other tumors in the same locality, all of which were more solid and less discrete and were composed of slender fusiform cells, apparently derived from the infundibulum. In this case the microscopic findings were quite different, and I do not know how to classify the tumor. The cells were rounded and fairly well stained, resembling

oligodendrocytes, but the gelatinous consistence of the tumor was unlike that of oligodendroglioma

DR TRACY B MALLORY Essentially, nothing was found in the rest of the body. There was a moderate degree of atelectasis of the lung, and the bronchi contained mucinous exudate, a finding that one would expect with the degree of respiratory difficulty that this child had had during life

CASE 33082

PRESENTATION OF CASE

A thirty-seven-year-old pregnant housewife entered the hospital in coma

A week before admission, during the sixth month of an apparently normal pregnancy, the patient had begun to complain of headache. Two days before admission a physician found the temperature to be 102°F. Since there was evidence of an upper respiratory infection, he ordered aspirin and phenacetin that day and again on the morning before admission, when the temperature was 100°F. The headache had increased by that time, and 15 mg of morphine was prescribed. At midnight relatives found the patient unresponsive and "stiff all over," with a temperature of 104°F and labored breathing. The family stated that she had passed little or no urine in the preceding two days, although she had taken fluids frequently. The physician injected 300,000 units of penicillin in oil before sending her to the hospital.

There had been no previous serious illness. The first pregnancy four years before admission had resulted in a miscarriage. Two years later a normal infant was born at full term.

On examination the patient was comatose, responding only to extremely painful stimuli. The pupils were markedly constricted. There was a purulent exudate in the nasal tract. The throat was red. Respirations were labored at 30 per minute. Breath sounds were diminished at the right lung base, and a few moist rales were heard low in both axillae. A soft apical systolic murmur and a Grade II systolic murmur were heard in the pulmonic area. The liver and spleen were not palpable. The uterine fundus rose to the level of the umbilicus. The fetal heart sounds were regular at a rate of 140 per minute. There was no vaginal discharge. The skin was clear, and no edema of the extremities was evident. The neck was not stiff, but the patient groaned when it was flexed. The tendon reflexes were hyperactive in the arms and in the left leg. There was no ankle clonus. The plantar reflex was equivocal on the right, and definitely extensor on the left.

The temperature was 99.8°F, the pulse 128, and the blood pressure 100 systolic, 60 diastolic.

Examination of the blood disclosed a hemoglobin of 12 gm per 100 cc and a white-cell count of 33,100, with 96 per cent neutrophils. The fasting blood sugar was 215 and the nonprotein nitrogen 22 mg per 100 cc, the carbon dioxide 16, the chloride 102 and the sodium 131.8 milliequiv per liter. The urine gave a +++ test for albumin. The sediment contained 3 to 5 white cells, rare red cells and 3 to 5 granular casts per high-power field. Thick, yellow spinal fluid was obtained by lumbar puncture. It contained 336,000 cells per cubic millimeter, with 95 per cent polymorphonuclears. Numerous gram positive lancet-shaped diplococci demonstrated on a smear were identified as Type 4 pneumococci. The same organism was grown from the blood. The spinal-fluid sugar was 16 and the protein 940 mg per 100 cc, the chloride was 112 milliequiv per liter. X-ray examination of the chest showed elevation of the right half of the diaphragm and mottled areas of increased density extending from low in the right hilus into the right costophrenic sinus. On the lateral view the right middle lobe appeared unusually dense.

Treatment consisted of intravenous and intrathecal penicillin and intravenous sulfadiazine and fluids. The spinal fluid gradually became less cloudy, and by the eleventh hospital day, it was clear and sterile, the sugar being 69 mg per 100 cc and the cell count 40 lymphocytes per cubic millimeter.

The patient's condition, however, did not correspond to the improved spinal-fluid findings. She never regained consciousness. Sulfadiazine had to be stopped twice because of oliguria and hematuria, although the urinary output never ceased completely. No rise in the nonprotein nitrogen resulted. Type 4 antipneumococcus rabbit serum injected on the third day apparently caused a rapid fall in the temperature to normal, but only a small amount of the serum was available. The temperature then ran between 99 and 101°F until the eleventh day, when it was again normal. There was some fluctuation in the lung signs, the rate and character of respirations and the depth of the coma, but at no time were the lungs free from signs of consolidation or atelectasis. On one occasion the extensor plantar response shifted from the left to the right, otherwise, there was no significant change in the neurologic signs. A male infant was born on the tenth day and lived only six hours.

On the thirteenth day the temperature began to rise, reaching 104 to 105°F, where it remained. The respirations were labored and rapid. On spinal puncture 30 cc of cloudy fluid containing 720 cells per cubic millimeter was obtained. No organisms grew from it. Terminally the count rose to 1200 cells per cubic millimeter, with 85 per cent polymorphonuclears. The patient died on the seventeenth day, having remained in coma during the entire period of hospitalization.

DIFFERENTIAL DIAGNOSIS

DR WIMAN RICHARDSON I do not usually ask questions, but there are a few that I should like to have answered in this case. The first is whether the pupils remained constricted or whether that condition can be attributed to morphine. Was the blood sugar taken before or after intravenous glucose was given? It is quite important to know whether the blood sugar was really elevated or whether the elevation was due to intravenous glucose. Is there any record of sulfonamide therapy during this period? How long after morphine was this examination done? The record indicates a considerable lapse of time, but I am not sure of that.

There is a little too much stress on the oliguria in this abstract.

The Babinski sign or plantar reflex, to my mind, is always equivocal so far as the diagnosis is concerned.

The hemoglobin was a low normal for a nonpregnant person. The blood picture, I suppose, is consistent with infection.

"At no time were the lungs free from signs of consolidation." No signs of consolidation were recorded so far as I can make out. There were diminished breath sounds and rales on one occasion, but consolidation is not mentioned.

"On one occasion the extensor plantar response shifted from the left to the right." Just like it!

A brief discussion of the symptoms is indicated. The onset of headache suggests the possibility of sinusitis. The history of the early oliguria, in spite of the adequate fluid intake, is something that must be explained. The clinical history is not suggestive of lobar pneumonia. There was a moderate acidosis, with a low carbon dioxide and a low blood sodium. I should like to ask Dr Butler at this point about the chloride of 102 milliequiv per liter. What happens to the chloride when the sodium is low? I should think that the chloride would have to be low.

DR ALLAN M. BUTLER Sodium and chloride are almost entirely independent. In plasma there are a variety of positively charged ions and a variety of negatively charged ions that exist almost totally dissociated as ions and are not combined as molecules.

DR RICHARDSON But the total has to be balanced?

DR BUTLER Yes, the total positive and negative ions must balance. In this patient the carbon dioxide was reduced from the normal of 26 to 16 milliequiv per liter. The chloride was normal. The sodium was somewhat low, but it is hard to say how low, because there is a variation in the normal sodium concentration of 136 to 147 milliequiv per liter by the method used in this case, just as there is a variation in the normal chloride from 100 to 107 milliequiv per liter. The carbon dioxide may

have been low because there was hyperventilation with the meningitis. Such hyperventilation would also tend to lower the sodium and to raise the chloride. Also, the ketosis of starvation might tend to lower the carbon dioxide. Thus, the changes in electrolyte concentrations are consistent.

The thing that is important is to use this case as a plea to stop asking the laboratory to test the spinal-fluid chloride when there is no possible information to be obtained from it. Unless one is dealing with a possible diagnosis of tuberculous meningitis, there is no rhyme or reason for requesting that determination, and even in cases of tuberculous meningitis, the chloride is of no help unless a simultaneous serum chloride is tested.

DR RICHARDSON I shall call attention to the lack of rise in the nonprotein nitrogen. And no dysuria was reported at any time.

With some diffidence, I am going to criticize the treatment. I do not like to do this as a rule, because hindsight is easier than foresight. I wonder, however, whether it was justifiable, in spite of the severity of the infection, to use the sulfonamides in the face of a marked oliguria. I should like to ask what the output was. And I should like to know whether or not the elevated blood sugar was important. I have in mind the possibility that the patient had moderate diabetes, which might have led to certain diseases. According to this chart that Dr Mallory has shown me, the output during the middle of the course of the illness was fairly good.

DR TRACY B. MALLORY I think that the oliguria followed the sulfonamide treatment rather than preceded it.

DR RICHARDSON The output was over 1500 cc, and one might be justified in giving sulfonamide in such a desperately sick patient. Another criticism is that there was a distinct likelihood of intracranial pressure and of cerebral disease in this patient, but from the record the possibility does not seem to have been investigated. There was undoubtedly some good reason, however. I think that there were lesions in the spinal canal and brain, possibly in the kidneys and possibly in the lungs. In the spinal canal we know that there was an acute purulent meningitis, due to the Type 4 pneumococcus. Was there disease in the brain? Pneumococcal meningitis could have resulted in obstruction at the foramen of the fourth ventricle — what do you call it, Dr Kubik?

DR CHARLES S. KUBIK The foramen of Magendie and Luschka.

DR RICHARDSON Obstruction can occur at that point and does so in certain types of meningitis, with a resulting internal hydrocephalus. Constricted pupils may, I believe, point to midbrain lesions. Dr Kubik will check me on that. This is the only evidence I find of localization of a brain lesion. On the other hand there is a distinct suggestion of sinusitis

in this case, and it is quite probable that the coma, which was the presenting symptom and never cleared, was due to a brain lesion, with increased intracranial pressure. The question is, Just what type of obstruction due to meningitis was this? Was it caused by a lesion pressing at the base of the brain? There is a definite possibility that this patient had a localized lesion. I suspect that the trouble started with ethmoiditis or infection in the sinuses, including the ethmoid, and I think that there might have been a localized abscess in the brain. There is little evidence on which to base such a diagnosis, except that the patient did not get well.

What about the kidneys, which seem to have been involved? In pregnancy the lesion described as diffuse cortical necrosis may occur. Terminally, there does not seem to be enough renal failure to allow for such a diagnosis. Recently, Robbins, Mallory and Kinney* described a disease known as necrotizing papillitis. Their cases occurred in conjunction with a severe infection in diabetic patients, and were not necessarily associated with pregnancy. One might consider glomerulonephritis as a result of infection, but, again, the picture in the case under discussion does not seem to have been that of glomerulonephritis. I think that the kidneys will show multiple abscesses, as a result of a septicemia due to the pneumococcus. There is no evidence of pyuria to go with multiple infections in the kidneys, but this possibility must be considered. Finally, it must be determined whether this patient had a sulfonamide nephrosis, with some renal failure. All the conditions that I have mentioned are questionable. I do not know how to make a definite statement.

What about the lung? I do not believe that there was any disease in the lung.

DR RICHARD SCHATZKI: There is one more film taken in bed in which there is definite abnormality in the right middle lobe, which is markedly decreased in size. There is atelectasis in the middle lobe and, in addition, disease in the lower lobe that also looks like atelectasis.

DR RICHARDSON: I am going to forget about the lungs. I think that they were "wet." I do not see clinical or x-ray evidence of pneumonia. There could have been a lesion to account for metastases to the brain or for meningitis. I do not see it. I say that this patient had a meningitis due to a Type 4 pneumococcus. I am sure of that. I believe that the cerebral lesion was an abscess, probably arising from a sinusitis. The kidneys will show small abscesses and possibly a sulfonamide nephrosis.

DR BUTLER: So far as the therapy is concerned, I should argue that it was correct to use the sulfonamides and penicillin. In administering sulfadiazine one ought, of course, to see to it that everything is done to maintain a proper urine volume. I do not

believe that a urine volume of 1500 cc must be present before one is justified in giving sulfonamides to such a patient as this. As I look at the chart of the urine output, the treatment appears justified.

DR MALLORY: The sulfonamides were given in two periods. The urinary output dropped, and treatment was stopped, it went up, and the sulfonamides were tried again.

DR RICHARDSON: I am sure that there is going to be something wrong with the kidneys.

CLINICAL DIAGNOSES

Meningitis³ due to Type 4 pneumococcus
Bronchopneumonia

DR RICHARDSON'S DIAGNOSES

Acute ethmoiditis
Acute meningitis (Type 4 pneumococcus)
Brain abscess
Multiple renal abscesses
Sulfonamide nephrosis?

ANATOMICAL DIAGNOSES

Acute sinusitis, left ethmoid and sphenoid
Bacterial endocarditis, mitral valve (Type 4 pneumococcus)
Multiple infarcts and abscesses of brain
Meningitis, pneumococcal, healing
Infarct of heart
Infarct of left kidney, healing
Bronchopneumonia, slight.

PATHOLOGICAL DISCUSSION

DR MALLORY: The primary lesion at autopsy was not mentioned by Dr Richardson, although he foretold many of the complications. It was an acute bacterial endocarditis of the mitral valve consequent to a pneumococcal septicemia that the patient had had at the start of the illness. Dr Richardson was correct in suspecting underlying sinusitis. There was severe chronic infection of the left ethmoid and sphenoid sinuses. There was little in the lung other than considerable atelectasis and a few small patches of terminal pneumonia. The long coma was explained when we examined the brain — there was almost no anatomical evidence of persisting meningitis, but on section innumerable areas of softening throughout the white matter were found, many of which seemed primarily to be infarction but a few of which contained enough leukocytes to be classified as abscesses. There had also been an embolism of the coronary arteries, and a considerable area of infarction was found. The kidneys were perfectly normal except for one small, almost healed infarct.

DR RICHARDSON: I do not see why you call bacterial endocarditis the primary lesion. I should think that it was secondary to the sinus infection, with septicemia, and then an implantation.

DR MALLORY: Yes, the sinuses were the portal of entry of the infection, but the endocarditis and the consequent multiple septic emboli to the brain were the basic lesions accounting for death.

THE RED CROSS. A HEALTH-PROMOTING AGENCY

THE opening rally of the 1947 Greater Boston Red Cross Fund will be held on February 27 at Symphony Hall. From then through March 26 all residents and workers of Greater Boston are being asked to contribute to the \$1,280,000 that is Greater Boston's part of the \$60,000,000 to be raised nationally by this great humanitarian organization. Of all money contributed, 75 per cent will go to serve veterans, servicemen and their families. The remainder will go for those regular Red Cross services of disaster relief, water safety, first aid, nutrition, nursing, transportation and other health and educational activities.

The American Red Cross is carrying a heavy load of responsibilities accumulated during the war. It

is helping to fulfill the many promises made by grateful citizens to their servicemen by aiding veterans both in hospitals and in their homes. The Army, Navy and Veterans Administration have provided for meeting the basic needs of the men and women in their installations. Situations arise, however, when there is need for equipment and supplies that cannot be obtained through official sources. As physicians are the first to realize, recovery from both physical and mental illnesses often depends on more than medicine or the best surgical skill. At the request of regular hospital personnel, the Red Cross provides carefully trained workers to help speed return to health and usefulness. It also furnishes supplies and equipment for making recovery and rehabilitation quicker and easier.

Despite continued nursing shortages nationally, 852 nurses served under Red Cross direction in seventy-four disasters in thirty-six states during 1945-1946. Sixteen floods in as many states, sixteen tornadoes in fifteen states, fourteen epidemics in thirteen states and thirteen major fires in nine states led the list of fiscal catastrophes. Disasters with proportionately fewer nursing needs were train wrecks, explosions, hurricanes and bus and other accidents.

The Red Cross also carried on a home-nursing program to promote better family and community health. Such training includes instruction in personal health, the care of mother and baby and the control of communicable diseases in the home and community. The objective is to train one person in every home to take care of minor illnesses under the doctor's orders and to realize that a minor illness may become a major illness unless proper nursing and medical care are given.

Red Cross public-health nursing services have been established in rural areas and small towns where other local health agencies had no plans or possibilities for organizing such a service. These public-health nursing services are established only after a careful study of community needs, consultation with state and local departments of health and the approval of the Area Red Cross office.

Red Cross first-aid training develops the knowledge and skill necessary for the care of the victim of an accident or sudden illness until the services of

a physician can be obtained. It has often meant the difference between life and death, between temporary and permanent disability or between rapid recovery and long hospitalization. It is also an important part of industrial safety programs, and reports from throughout the Nation indicate that such training frequently curtails the number of lost-time accidents by as much as 50 per cent.

The Red Cross is a health-promoting agency — in the home, in the hospital, on the highway. It gives food to those in other countries left starving by war and disaster. It teaches food preservation and good nutrition to the housewives of this country. Its financial assistance helps many a veteran's or serviceman's family when the need arises or over a temporary period until a Government claim or other plan can be established. It also brings comfort, nursing service and help to veterans, servicemen and civilians in hospitals throughout the country. In other words, the Red Cross gives service and help wherever there is need. Physicians should continue to support this great humanitarian organization!

Q FEVER

DURING the past two years, while the search continued for the agent or agents that are responsible for the disease known as "virus pneumonia," considerable information has accumulated concerning the occurrence of the specific rickettsial disease Q fever as a cause of some severe types of atypical pneumonia. Most of the new information regarding this disease was collected by workers in Army hospitals and laboratories and has been published only recently. The identity of the agent and some aspects of its epidemiology and pathogenicity have come to light during the last decade.

In 1937, Derrick¹ described an influenza-like infection occurring among meat workers that had come into prominence since 1935 in Queensland, Australia, he called the disease "Q fever." The causative agent was isolated by the intraperitoneal injection of guinea pigs with the blood and urine obtained from patients during the acute stage of the disease. The agent was studied in detail by Burnet and Freeman,² who showed it to be a filter-passing rickettsia. They showed that specific antibodies

developed toward the end of the second week of illness and could be demonstrated by the agglutination of suitable suspensions of the rickettsia. Infection with the rickettsia was found to be widespread in a native rodent, the bandicoot, which served as a reservoir, with certain ticks acting as vectors. Forest workers and cattle were infected directly by infected ticks, and slaughterhouse workers were thought to be infected by the inhalation of dried feces of ticks infected from the cattle.³ Pneumonia was not recognized as a feature of Q fever in the Australian cases. The organism was named *Rickettsia burneti*.

An agent similar to *R. burneti* was isolated at about the same time by workers in the Rocky Mountain Laboratory of the United States Public Health Service from ticks collected in Montana and Wyoming.⁴ A disease corresponding to Australian Q fever is known to occur in this area, and serologic evidence of infection with the agent was found in persons over a large area of the United States, ranging from Nebraska to Texas and Washington.⁵ In 1940, an outbreak of pneumonitis due to the organism of Q fever occurred at the National Institute of Health in Bethesda, Maryland.⁶

The studies made by the Army workers have been recently reported in detail.⁷ During the winter of 1944-1945 outbreaks of severe atypical pneumonia occurred among British troops stationed in the Mediterranean area and also among American military units in Corsica. The disease differed in some important respects from the atypical pneumonia that was prevalent in the United States and Great Britain. It seemed to be sharply limited to particular units and areas and was characterized by a high attack rate, — up to 50 per cent, — and there was no associated increase in cases of minor respiratory illnesses. The clinical and epidemiologic findings were readily corroborated when an opportunity arose to investigate an outbreak among the members of a British parachute regiment who had acquired the infection in Athens. Although the studies in that outfit began when the outbreak was subsiding, it was possible to identify its nature in retrospect by the laboratory examination of serum specimens from patients.

Four similar outbreaks were investigated among American military units stationed in Italy near Florence and Bologna. The rickettsia of Q fever was isolated from the blood of some of the patients in these outbreaks and was shown to be the cause of the outbreaks. At the same time it was demonstrated serologically that about three fourths of the sporadic cases of atypical pneumonia in the same region were, in fact, cases of Q fever. These laboratory studies were carried out chiefly in the Fifteenth Medical General Laboratory which was serving this area.

At about the same time it was also learned that an outbreak of a severe influenza-like infection associated with atypical pneumonia had occurred during the preceding winter in Athens. The Germans, who seemed to be more severely affected than the natives, called it the "Balkan gripe." Dr J. Caminopetros, of the Pasteur Institute of Greece, was able to establish a transmissible febrile illness in guinea pigs by the inoculation of blood from a patient obtained during the acute stage of the disease. One of these guinea pigs was later brought to the laboratories of the Commission on Acute Respiratory Disease at Fort Bragg, North Carolina, where the rickettsia of Q fever was isolated and identified.

During May and June, 1945, other outbreaks occurred among certain units that were being returned to the United States from southern Italy. One of these was studied by the medical officers at Camp Patrick Henry, Virginia, and the etiologic and epidemiologic aspects were investigated by the Commission on Acute Respiratory Diseases. The cause of this outbreak was identified as the Balkan-gripe type of *R. burneti*.

Outbreaks of severe atypical pneumonia occurred among the personnel of the two laboratories in which these investigations were being carried out. The one in the Fifteenth Medical General Laboratory was shown by isolation of the agent and by serologic studies, to have been due to the Italian strain of *R. burneti*, and similar studies in the Fort Bragg laboratory indicated that the infections there were caused by the Balkan strain. There were no deaths among these cases.

Another possible focus of Q fever was suggested by the report of a case of atypical pneumonia in a

military hospital in Panama. Serologic studies of the blood of the patient and of the agent that was isolated from the blood indicated that the disease was caused by a strain of the American type of Q fever. The patient had been in Panama for several months prior to his illness.

A preliminary report has also appeared about an outbreak of Q fever that occurred in Amarillo, Texas, in May, 1946.⁸ There were more than 40 cases. Most of them occurred in men who were employees of a stockyard and meat-packing company, but some were observed among railroad workers and others around the stockyards. There were 2 deaths in this outbreak.

The strains of *R. burneti* isolated from the various outbreaks have many characteristics in common. Antigenic differences among these strains have been partially worked out by investigators at the National Institute of Health. These differences suggest that Q fever may be more prevalent in the United States than was previously suspected and that cases may have been missed because of the improper selection of strains for the serologic tests.

MASSACHUSETTS MEDICAL SOCIETY

TREASURER'S OFFICE

All members should be reminded that the proportion of the refund returned to each district society is based on the number of dues paid by March 1 in that district, and also that the names of members who have not paid their dues by March 1 are automatically removed from the mailing list of the *Journal* until such dues are paid.

ELIOT HUBBARD, JR., *Treasurer*

DEATH

JOHNSON — Herbert L. Johnson, M.D., of Hadley, died January 22. He was in his eighty-eighth year. Dr. Johnson received his degree from Bowdoin Medical School in 1884.

POSTGRADUATE LECTURE COURSE

The review Postgraduate Lecture Course, which has been arranged by the Committee on Postgraduate Medical Education, Massachusetts Medical Society, in co-operation with the Massachusetts Department of Public Health, will begin on March 3. The meetings will be held at Sanders Theater in Memorial Hall, Harvard University, Cambridge. These lectures are primarily designed for general practitioners, but medical officers, hospital interns and residents, and postgraduate and undergraduate medical students are cordially invited to attend. Recent progress in medicine will be discussed, and the speakers have been urged to present their subjects in a simple and direct manner and to emphasize diagnosis and treatment from the point of view of the physician in general practice.

All those who plan to attend but have not enrolled should do so immediately by either returning the post card recently forwarded to all physicians in Massachusetts or addressing a post card or letter directly to the Postgraduate Lecture Course Committee, Massachusetts Medical Society, 8 Fenway, Boston 15.

The detailed program for the course is as follows

REVIEW LECTURE COURSE

Monday, March 3 5 30-5 45 **OPENING REMARKS** Dwight O'Hara president, Massachusetts Medical Society, dean, Tufts College Medical School

MEDICAL ASPECTS OF ATOMIC WARFARE *Chairmen* Shields Warren and Stafford L. Warren

5 45-6 45 Medical Implications of the Bikini Experiments. Capt. George M. Lyon (MC), USNR, assistant to the Surgeon General, Navy Department Washington, D. C., representative, Bureau of Medicine and Surgery, U. S. N., Joint Task Force One

7 00-7 30 Buffet Supper

7 30-8 00 The Pathology of Atomic-Bomb Injuries Shields Warren formerly, director of medical research, Bikini Project, pathologist, New England Deaconess and New England Baptist hospitals

8 00-8 30 General Aspects of Atomic Energy Stafford L. Warren formerly, medical director, Manhattan Project, professor of radiology, University of Rochester Medical School, Rochester, New York

8 30-9 00 Motion pictures of Bikini Experiment

Wednesday, March 5 INFECTIOUS DISEASES *Chairmen* Maxwell Finland and Conrad Wesselhoft

3 00-3 35 Rubella and Congenital Deformities — The present problem Conrad Wesselhoft physician-in-chief, Haynes Memorial, Massachusetts Memorial Hospitals, clinical professor of communicable diseases, Harvard Medical School and Boston University School of Medicine

3 35-4 10 Pneumonias Maxwell Finland chief, Fourth Medical Service, and associate physician, Thorndike Memorial, Boston City Hospital, assistant professor of medicine, Harvard Medical School

4 10-4 45 Meningitis Louis Weinstein visiting physician, Haynes Memorial, Massachusetts Memorial Hospitals, assistant professor of medicine, Boston University School of Medicine

4 45-5 10 Intermission

5 50-5 25 Use of Gamma Globulin Charles A. Janeway professor of pediatrics, Harvard Medical School, chief, Medical Service, Children's Hospital

5 25-6 00 Prophylactic Inoculations Geoffrey Edsall instructor in bacteriology and applied anatomy, Harvard Medical School, assistant director, Division of Biologic Laboratories, Massachusetts Department of Public Health

Monday, March 10 PART I CHEST DISEASE *Chairmen* Theodore L. Badger and Reeve H. Betts

5 30-6 00 The Role of Surgical Exploration in the Diagnosis and Treatment of Intrathoracic Lesions Reeve H. Betts assistant professor of surgery, Tufts College Medical School

6 00-6 30 The Value of Streptomycin and BCG in the Treatment and Prevention of Tuberculosis. Lowrey F. Davenport instructor in medicine, Harvard Medical School

6 30-7 00 The Management of Suppurative Diseases of the Lung John W. Strieder associate professor of surgery, Boston University School of Medicine, chief, Thoracic Surgery, Boston City Hospital, visiting surgeon in charge of thoracic surgery, Massachusetts Memorial Hospitals

7 00-7 30 Buffet Supper

PART II NEUROSURGICAL DISEASE *Chairmen* Gilbert Horrax and James C. White

7 30-8 00 The Neurosurgical Treatment of Pain James C. White assistant professor of surgery, Harvard Medical School, chief of neurosurgical service, Massachusetts General Hospital

8 00-8 30 The Treatment of Spinal-Cord Injury Donald Munro associate professor of neurosurgery, Boston University School of Medicine, assistant professor of neurosurgery, Harvard Medical School, surgeon-in-chief and Head of Department of Neurosurgery, Boston City Hospital

8 30-9 00 The Diagnosis and Treatment of Brain Tumors Gilbert Horrax chief of Department of Neurosurgery, Lahey Clinic, neurosurgeon to New England Deaconess and New England Baptist hospitals

Wednesday, March 12 INFANTILE PARALYSIS AND BACK PAIN *Chairmen* William T. Green and Arthur A. Thibodeau

3 00-3 25 Epidemiology of Infantile Paralysis Charles A. Janeway professor of pediatrics, Harvard Medical School, chief, Medical Service, Children's Hospital

3 25-3 50 Diagnosis and Early Care of Infantile Paralysis Thomas Gucker assistant in orthopedic surgery, Children's Hospital

3 50-4 15 The Treatment of Infantile Paralysis during Convalescence David S. Grice junior attending orthopedic surgeon, Children's Hospital and Peter Bent Brigham Hospital, assistant in Department of Orthopedics, Harvard Medical School, assistant director, Massachusetts Infantile Paralysis Clinics

4 15-4 30 The Chronic Stage of Infantile Paralysis — Rehabilitation William T. Green assistant professor of orthopedics, Harvard Medical School, orthopedic surgeon-in-chief, Children's Hospital

4 30-4 40 Intermission

4 40-5 05 Body Mechanics, Examination of the Back, Postural Back Ache James W. Toumey orthopedic surgeon, Lahey Clinic, New England Baptist and New England Deaconess hospitals

5 05-5 30 Acute Back Strain and Other Causes of Back Pain Arthur A. Thibodeau instructor in orthopedics, Tufts College Medical School

5 30-6 00 Sciatica and Rupture of Intervertebral Disk Joseph S. Barr clinical professor of orthopedic surgery, Harvard Medical School, chief of Orthopedic Staff, Massachusetts General Hospital

Monday, March 17 MINOR SURGERY AND SURGICAL SHOCK
Chairmen Augustus Thorndike and C. Stuart Welch

5 30-6 15 **Injuries of the Hand** Examination, diagnosis and early treatment Henry C. Marble assistant in surgery, Harvard Medical School, visiting surgeon, Massachusetts General Hospital surgeon-in-chief, Chelsea Memorial Hospital

6 15-7 00 **Infections of the Skin — Pustular Acne, Furunculosis and Carbuncles** Joseph Tartakoff assistant professor of surgery, Tufts College Medical School, assistant visiting surgeon, Boston City Hospital

7 00-7 30 **Buffet Supper**

7 30-8 00 **Sprains, Strains and Contusions Pathology and treatment** Thomas B. Quigley associate in surgery, Harvard Medical School and Peter Bent Brigham Hospital

8 00-8 30 **Surgical Shock** John E. Dunphy associate in surgery, Harvard Medical School, visiting surgeon, Peter Bent Brigham Hospital

8 30-9 00 **Burns of the Hand** Early and late treatment Melvin F. White assistant professor of surgery, Tufts College Medical School, visiting surgeon, St. Elizabeth's Hospital, plastic surgeon, Tumor and Surgical Departments, Boston Dispensary

Wednesday, March 19 ANESTHESIA AND ITS COMPLICATIONS
Chairmen Henry K. Beecher and Morris J. Nicholson

3 00-3 40 **Current Trends in the Use of General Anesthesia** M. Gene Black anesthetist, Massachusetts Memorial Hospitals, instructor in anesthesiology, Boston University School of Medicine

3 40-4 20 **Management of the Patient under Spinal Anesthesia** Leo V. Hand anesthetist, New England Deaconess Hospital

4 20-4 40 **Intermission**

4 40-5 20 **Postanesthetic Complications** Morris J. Nicholson Department of Anesthesiology, Lahey Clinic, anesthetist, New England Deaconess and New England Baptist hospitals

5 20-6 00 **Evaluation and Care of the Patient in Shock** Henry K. Beecher anesthetist-in-chief, Massachusetts General Hospital, Henry I. Dorr Professor of Research in Anesthesia, Harvard Medical School

Monday, March 24 ENDOCRINOLOGY, INCLUDING DIABETES
Chairmen Richard P. Stetson and George W. Thorn

5 30-6 00 **Carbohydrate Metabolism** Recent concepts Richard P. Stetson associate in medicine, Harvard Medical School, assistant visiting physician, Boston City Hospital

6 00-6 30 **Diabetes Mellitus** Degenerative complications Alexander Marble instructor in medicine, Harvard Medical School, physician, New England Deaconess Hospital

6 30-7 00 **Adrenal Insufficiency** Diagnostic criteria George W. Thorn Hersey Professor of Theory and Practice of Physic, Harvard Medical School, physician-in-chief, Peter Bent Brigham Hospital

7 00-7 30 **Buffet Supper**

7 30-8 00 **Thyrotoxicosis — Pathologic Physiology** Rulon W. Rawson associate in medicine, Harvard Medical School, assistant physician, Massachusetts General Hospital

8 00-8 30 **Thyrotoxicosis — Evaluation of Treatment with Thiouracil Compounds** Robert H. Williams associate in medicine, Harvard Medical School, junior visiting physician, Boston City Hospital

8 30-9 00 **Postmenopausal Osteoporosis** Fuller Albright associate professor of medicine, Harvard Medical School, physician, Massachusetts General Hospital

Wednesday, March 26 GYNECOLOGY AND STERILITY
Chairmen Samuel R. Meaker and Fred A. Simmons

3 00-3 25 **Management of Dysmenorrhea** Somers H. Sturgis assistant surgeon, Massachusetts General Hospital, assistant in gynecology, Harvard Medical School

3 25-3 50 **Habitual Abortion** Arthur T. Hertig pathologist, Boston Living-in Hospital and Free Hospital for Women, assistant professor of pathology and obstetrics, Harvard Medical School

3 50-4 15 **Ovulation Timing** Fred A. Simmons assistant surgeon, Massachusetts General Hospital and Free Hospital for Women, assistant in gynecology, Harvard Medical School

4 15-4 30 **Intermission**

4 30-5 00 **Depressed Respiratory Metabolism and Low Fertility** Samuel R. Meaker gynecologist, Massachusetts Memorial Hospitals, professor of gynecology, Boston University School of Medicine

5 00-5 30 **Ovarian Hormone Therapy** Max Davis obstetrician and gynecologist, Massachusetts Memorial Hospitals, assistant professor of obstetrics and gynecology, Boston University School of Medicine

5 30-6 00 **Findings and Results in a Series of Sterility Cases** A. Seymour Parker, Jr. physician, Medical Department, Lahey Clinic

Monday, March 31 OBSTETRICS
Chairmen Roy J. Heffernan and Frederick C. Irving

5 30-5 50 **Diet in Pregnancy** Bertha L. Burke assistant professor of maternal and child nutrition, Harvard School of Public Health

5 50-6 20 **The Rh Factor** Louis K. Diamond assistant professor of pediatrics, Harvard Medical School, visiting physician, Children's Hospital

6 20-6 40 **New Developments in Prenatal Care** Charles L. Sullivan assistant obstetrician St. Elizabeth's Hospital and Massachusetts General Hospital

6 40-7 00 **Induction of Labor** Roy J. Heffernan visiting obstetrician and gynecologist, Carver Hospital, consulting obstetrician and gynecologist, Faulkner Hospital and St. Margaret's Hospital

7 00-7 30 **Buffet Supper**

7 30-7 50 **The Use of X-Ray in Obstetrics** Daniel J. McSweeney assistant professor of obstetrics, Boston University School of Medicine and Tufts College Medical School, visiting obstetrician, Boston City Hospital and St. Margaret's Hospital

7 50-8 10 **The Fetus during Labor** Charles L. Sullivan

8 10-8 30 **Extrauterine Pregnancy** Daniel J. McSweeney

8 30-8 50 **Indications for Forceps Delivery** Roy J. Heffernan

Wednesday, April 2 GASTROENTEROLOGY
Chairmen Franz J. Ingelfinger and Chester M. Jones

3 00-3 25 **Procedures in Diagnosis and Management of Peptic Ulcer** Franz J. Ingelfinger associate professor of medicine, Boston University School of Medicine, chief, Gastrointestinal Outpatient Department, Massachusetts Memorial Hospitals, member of staff, Robert Dawson Evans Memorial Hospital

3 25-3 50 **Medical Management of Peptic Ulcer** Sara M. Jordan director of gastroenterology, Lahey Clinic, physician, New England Baptist and New England Deaconess hospitals

3 50-4 15 **Surgical Management of Peptic Ulcer** Francis D Moore associate in surgery, Harvard Medical School, assistant surgeon, Massachusetts General Hospital

4 15-4 30 **Intermission**

4 30-5 05 **Diagnostic and Medical Measures Pertinent to the Problem of Painless Jaundice** Chester M Jones clinical professor of medicine, Harvard Medical School, physician, Massachusetts General Hospital

5 05-5 40 **Surgical Measures in Relation to Painless Jaundice** Reginald H Smithwick professor of surgery, Boston University School of Medicine, surgeon-in-chief, Massachusetts Memorial Hospitals, member of board of consultants, Massachusetts General Hospital

5 40-6 00 **Discussion**

Monday, April 7. PART I OFFICE PROCEDURES IN ANORECTAL DISEASE *Chairmen* E Parker Hayden and Neil W Swinton

5 30-5 45 **Differential Diagnosis of Rectal Bleeding and Methods of Rectal and Colon Examinations** E Parker Hayden chief, Proctologic Clinic, and assistant visiting surgeon, Massachusetts General Hospital

5 45-6 00 **Hemorrhoids** Roy E Mabrey assistant surgeon, Massachusetts General Hospital

6 00-6 10 **Anal Fissure** Roy E Mabrey

6 10-6 25 **Anorectal Abscess and Fistula** E Parker Hayden

6 25-6 40 **Premalignant Lesions of the Rectum and Colon** Neil W Swinton surgeon, Lahey Clinic, New England Deaconess and New England Baptist hospitals

6 40-7 00 **Anal Pruritus** Neil W Swinton

7 00-7 30 **Buffet Supper**

PART II RADIATION THERAPY *Chairmen* Joseph H Marks and Samuel A Robins

7 30-7 45 **Contact Therapy of Superficial Lesions** Bernard E LeVine radiation therapist, Beth Israel Hospital

7 45-8 00 **Hodgkin's Disease** Hugh F Hare director, Department of Radiology, Lahey Clinic

8 00-8 15 **Fibroids and Menorrhagia** Samuel A Robins professor of radiology, Tufts College Medical School, chief radiologist, Beth Israel Hospital and Evangeline Booth Hospital

8 15-8 30 **Carcinoma of the Cervix** Laurence L Robbins roentgenologist, Massachusetts General Hospital

8 30-8 45 **Carcinoma of the Ovary** Joseph H Marks instructor in radiology, Harvard Medical School, radiologist, New England Deaconess and Palmer Memorial hospitals

8 45-9 00 **Discussion**

Wednesday, April 9 DISEASES OF BLOOD AND LYMPH NODES *Chairmen* William Dameshek and Thomas H Ham

3 00-3 30 **Diagnosis of Anemia** Thomas H Ham assistant professor of medicine, Harvard Medical School, associate physician, Thorndike Memorial, and junior visiting physician, Boston City Hospital

3 30-4 00 **Treatment of the Anemias** Maurice B Strauss chief of medical service, Cushing General Hospital, Framingham

4 00-4 35 **Diagnosis and Treatment of Disorders of the Spleen** William Dameshek professor of clinical medicine, Tufts College Medical School, hematologist, Pratt Diagnostic Hospital, chief, Blood Clinic, Boston Dispensary

4 35-4 45 **Intermission**

4 45-5 15 **Treatment of Leukemia** Henry Jackson, Jr associate physician, Thorndike Memorial, Boston City Hospital, assistant professor of medicine, Harvard Medical School

5 15-5 45 **Transfusion Therapy** Charles P Emerson assistant professor of medicine, Boston University School of Medicine, member of staff, Massachusetts and Evans Memorial hospitals

5 45-6 00 **Discussion**

Monday, April 14 THE PREVENTION OF VENOUS THROMBOSIS AND PULMONARY EMBOLUS *Chairmen* Arthur W Allen, James A Evans and John Homans

5 30-6 00 **Clinical Features of Pulmonary Embolism** Lewis Dexter assistant in medicine, Harvard Medical School, senior associate in medicine, Peter Bent Brigham Hospital

6 00-6 30 **Experiences with Heparin in Pitkin's Menstruum Combined with Dicumarol in the Treatment of Venous Thrombosis** James A Evans physician, Lahey Clinic, physician, New England Baptist and New England Deaconess hospitals

6 30-7 00 **Anticoagulant Drugs versus Vein Ligation in the Treatment of Thrombophlebitis at the Beth Israel Hospital** Arnold Starr junior visiting surgeon, Beth Israel Hospital

7 00-7 30 **Buffet Supper**

7 30-8 00 **Three-year Study of Rest, Exercise and Early Ambulation Relative to Venous Thrombosis** Analysis of 2000 consecutive cases James C McCann surgeon, St Vincent's Hospital, Worcester.

8 00-8 30 **Prophylactic Femoral-Vein Division at the Massachusetts General Hospital** Robert R Linton visiting surgeon and chief, Peripheral Vascular Clinic, Massachusetts General Hospital, associate in surgery, Harvard Medical School

8 30-9 00 **The Prophylactic Use of Dicumarol in Gynecology** George Van S Smith professor of gynecology, Harvard Medical School, chief, Free Hospital for Women

Wednesday, April 16 PART I KIDNEY DISEASE *Chairmen* Reginald Fitz and W Richard Ohler

3 00-3 30 **Diagnosis of Renal Disease** Laurence B Ellis associate in medicine, Harvard Medical School, assistant visiting physician, Boston City Hospital

3 30-4 30 **Treatment of Renal Disease** Reginald Fitz lecturer on the history of medicine, Harvard Medical School, consulting physician, Peter Bent Brigham Hospital, and W Richard Ohler, assistant professor of medicine, Harvard Medical School, chief, Second Medical Service, Boston City Hospital

4 30-4 35 **Intermission**

PART II HYPERTENSION *Chairmen* Robert S Palmer and Reginald H Smithwick

4 35-5 00 **The Heart in Hypertension** Paul D White clinical professor of medicine, Harvard Medical School, physician, Massachusetts General Hospital

5 00-5 30 **The Value of Various Therapeutic Measures in the Management of Hypertension and Hypertensive Cardiovascular Disease** Robert S Palmer associate physician, Massachusetts General Hospital, consultant, Massachusetts Eye and Ear Infirmary

5 30-6 00 **Surgical Measures in Hypertensive Patients** Reginald H Smithwick professor of surgery, Boston University School of Medicine, surgeon-in-chief, Massachusetts Memorial Hospitals

Monday, April 21. CARDIOVASCULAR DISEASES *Chairmen* Samuel A Levine and Howard B Sprague

5 30-6 00 **Pericarditis** Howard B Sprague instructor in medicine, Harvard Medical School, associate physician, Massachusetts General Hospital, chief of medicine, House of the Good Samaritan

6 00-6 30 **The Diagnosis of Coronary-Artery Disease** James M Faulkner professor of medicine, Tufts College Medical School

6 30-7 00 **The Treatment of Cardiac Emergencies** Paul D White clinical professor of medicine, Harvard Medical School, physician, Massachusetts General Hospital

7 00-7 30 **Buffet Supper**

7 30-8 00 **The Clinical Features of Patent Ductus Arteriosus** Samuel A Levine assistant professor of medicine, Harvard Medical School, physician, Peter Bent Brigham Hospital

8 00-8 30 **The Heart in Acute Infections** Charles A Janeway professor of pediatrics, Harvard Medical School

8 30-9 00 **The Treatment of Subacute Bacterial Endocarditis** Chester S Keefer professor of medicine, Boston University School of Medicine, director, Evans Memorial, Massachusetts Memorial Hospitals

Wednesday, April 23 **PEDIATRICS** Chairmen Stewart H Clifford and Richard C Tefit, Jr

3 00-3 45 **Influenza Meningitis Diagnosis and treatment** John A V Davies assistant professor of pediatrics, Harvard Medical School

3 45-4 30 **Factors Influencing the Growth and Development of the Fetus** Clement A Smith assistant professor of pediatrics, Harvard Medical School

4 30-4 40 **Intermission**

4 40-5 15 **Influence of Disease on the Growth and Development of the Child** Stuart S Stevenson associate in child health, Harvard Medical School and Harvard School of Public Health

5 15-6 00 **Influence of Endocrine Dysfunction on Acceleration or Retardation of Growth and Development in the Child and Adolescent** Nathan B Talbot assistant professor of pediatrics, Harvard Medical School

CORRESPONDENCE

PSYCHOSOMATIC MEDICINE

To the Editor I really enjoyed the excellent editorial on the meaning of psychosomatic medicine, which appeared in the January 9 issue of the *Journal*. In numerous places I have protested against the absurdities that the term "psychosomatic medicine" has somehow launched into clinical thinking. The effect of emotions, as organic events, on bodily structure is as old as Hippocrates, and long before Dunbar's book this was stressed in the literature by both experimental and clinical workers. Of course, all emotions are potent organic events, just as all experience changes bodily structure either transiently or permanently.

It is a far cry from this, however, to the fantastic ideas that the psychosomaticists have introduced into medicine. A misstep morally makes one slip on the ice twenty years later and break an ankle or the neck as a punishment self-inflicted by unconscious guilt. All kinds of nonstatistical and utterly unproved work asserts that this or that aggressive or non-aggressive trait is responsible for accidents, heart disease, ad lib, ad glib, and ad nauseum. The pediatricians, the orthopedic surgeons, the internists, indeed all kinds of physicians have taken it up so that, as one lady expressed it to me recently, it is rather dangerous to consult about a bodily disease at present, for you are accused of all kinds of things that have occurred in your childhood.

I plead guilty, for I have already introduced the word "somatopsychics" into the literature via two papers one of which was published with that name as part of the title. I agree that neither psychosomatics nor somatopsychics is a necessary word. I believe, however, that merely stating that

an experience, of whatever sort, creates bodily disorder is insufficient since the "experienter" is as important as the "experience." There are people with constitutions predisposed to fear, depression and disastrous somatic responses to experience. Whether the constitution is acquired early through conditioning or inheritance is important, but the treatment does not depend finally and fundamentally on psychologic grounds—it rests on reorganizing physiology. That there is a bodily basis to the mental diseases, whether they are organic or functional is, so far as I am concerned, the proper working hypothesis of psychiatry. Every emotional experience activates bodily changes, and even if mental disease can be traced to emotional experiences, the bodily changes would still have to be understood and accounted for to bring about cure.

Psychosomatics talks much but cures little. The real therapeutic triumphs in psychiatry, as yet imperfect, are physiologic—insulin coma, electric and metrazol shock, prefrontal lobotomy and the use of Dilantin and other drugs. There are few who can live with an emotionally placid mood in an extremely troubled world.

BOOK REVIEWS

Local Health Units for the Nation. A report. By Haven Emerson, M D. With the collaboration of Martha Lubinbuhl, M A. 4th paper, 333 pp., illustrated. New York: The Commonwealth Fund, 1945. \$1.25.

This book is the report of the Subcommittee on Local Health Units of the Committee on Administrative Practice of the American Public Health Association. It discusses the existing local public-health services in the various states and makes suggestions for improved service. The book is largely composed of tables showing existing personnel and annual budgets for local health services, together with similar tables for an improved service. Each state is discussed separately.

This volume should be of value to health administrators, physicians and lay persons interested in improving public health.

Public Medical Care Principles and problems. By Franz Goldman, M D. 8th, cloth, 226 pp. New York: Columbia University Press, 1945. \$2.75.

In this volume the author considers the problem of adequate medical care, describing the facilities that have been utilized in various countries in the past four centuries. The evolution of the public hospital, the transition from the primitive dispensary to the public medical center and the various methods employed in medical programs for persons in need are discussed.

In the last chapter the author outlines his solution of the problem as follows:

It appears, then, that there is only one single method that would avoid the disadvantages inherent in other approaches to the problem of organizing payment for facilities and services: public medical care for all, with every necessary service provided as a right and free of charge. Such a system exists in Russia.

Regardless of whether one agrees or disagrees with the author's plan for medical care, his presentation of the changing patterns of medical service makes this book worth reading, and the extensive bibliography enhances its value.

Mitchell-Nelson Textbook of Pediatrics Edited by Waldo E. Nelson, M.D. 4th, cloth, 1350 pp., with 519 illustrations, 26 in color. Fourth edition, revised. Philadelphia and London: W. B. Saunders Company, 1945. \$10.00.

This composite authoritative standard treatise, the work of forty-nine contributors, first published in 1933 and last revised in 1941, has been completely rewritten and to all intents and purposes is a new book. Some alteration has been made in the general arrangement, a number of new sections have been added, and some sections of the previous editions have been discarded. It has been the aim of the editor to provide a textbook for the undergraduate medical student, the pediatrician and the general practitioner. The text is printed in a two-column format, with a good type on heavy paper. The volume because of its weight is difficult to handle. It is suggested that future editions or printings be made with a lighter paper, especially because the illustrations do not require the heavy paper. The book is recommended for all medical reference collections and to physicians interested in pediatrics.

The Physician's Business: Practical and economic aspects of medicine. By George D. Wolf, M.D. With a foreword by Harold Rypins, M.D. Second edition. 8th, cloth, 433 pp., with 58 illustrations. Philadelphia: J. B. Lippincott Company, 1945. \$6.00.

Medicine is undoubtedly an altruistic profession in many ways, but the physician is entitled to a just compensation for his services. Dr. Wolf has analyzed medicine as a business and in this book has made his studies available to the medical profession. This second edition has been thoroughly revised wherever possible. New chapters on workmen's compensation laws and prepaid health insurance have been added, but the material on postgraduate study and war careers for physicians other than private practice have remained unaltered, because of the changing situation in these fields. The location of a practice, contacts with other physicians, specialization and the proper conduct of an office, including finance and insurance, are adequately discussed in a simple manner. There is an important chapter on the legal relations of the physician to his patients and the community. This book should prove of value to all physicians and should be in all medical and business libraries.

Hypnoanalysis. By Lewis R. Wolberg, M.D. With a foreword by A. Kardiner, M.D. 8th, cloth, 342 pp. New York: Grune and Stratton, 1945. \$4.00.

The first part of this book comprises a complete report of a hypnoanalysis in an individual case of schizophrenia, with a dynamic interpretation of the protocol, involving the use of hypnosis as a therapeutic agent and resulting in a return of the patient to normal. The second is devoted to an extended consideration of the theory and practice of hypnoanalysis, including the relation of psychoanalysis and hypnosis.

The Psychoanalytic Theory of Neurosis. By Otto Fenichel, M.D. 8th, cloth, 703 pp. New York: W. W. Norton & Company, Inc., 1945. \$7.50.

This book is in all respects an informative, systematized, reference text in psychoanalysis. The title is thus quite incomplete and perhaps misleading, not only the psychoanalytic theory of neurosis but also nearly all aspects of the psychoanalytic field in the frequently encountered psychogenic disorders are dealt with. Practically every phase—in fact almost every statement—is bibliographically covered and referentially indexed, so that there is no doubt left for the reader concerning where the weight of the opinion and experience of other workers and the author is directed.

A detailed description of the book would necessitate a repetition of the chapter headings. The development, description and therapeutic consideration of so-called "functional" emotional illnesses, however, are delivered so painstakingly and concisely that at times the reader may believe that Dr. Fenichel is giving him a personal series of lectures in these subjects. The abundantly illustrative case material does not tax the reader to find the desired examples.

Depending on the background of the reader, a certain amount of dissension may arise with the inclusion of manic depressive and schizophrenic syndromes and standard psycho-

pathic personality pictures (character disorders) in a psychoanalytic text. The descriptions of these conditions are not presented, but the pathogenesis of each major symptom is discussed according to psychoanalytic principles. The terms used in the following typical description may be somewhat distorted so as to reflect chiefly analytic principles: "The hypertrophy of the reassuring infantile partial instinct simultaneously serves as a safeguard to maintain the repression of the Oedipus complex and of other warded off remainders of infantile sexuality." A tilt with a wooden spear is made against "constitutional determinists" who employ Latin neologisms in the discussion of fixation.

Schizophrenia, as is frequently done, is dealt with as a repression, extending back, at least in part, to the narcissistic level. The important symptoms of schizophrenic psychoses are analyzed and, in a sense, genitalized. Hallucinations are considered capable of interpretation in the same way as dreams. Delusions are regarded as misjudgments of reality based on projection—representing an attempt to supplant the last parts of reality, they often contain elements of the repudiated reality and portions of warded off drives as well as projected demands of the superego. Paranoia and paranoid schizophrenia are believed to differ in that in the former "a more fortunate constellation of psychological forces permits a definite encapsulation of the pathological process."

Echolalia, echopraxia and automatic obedience are also attributed to primitive attempts at regaining contact. The infantile "mimetic expressions" are considered in apposition to simultaneous "warded-off hostile impulses" and "magic gestures" indicating "desired behavior of other persons in the future." Catatonic rigidity is held to reflect a conflict between the impulse to act and the defense against it. Borderline cases are discussed without—in the reviewer's opinion—the careful directiveness that characterizes the bulk of the text, issue may be taken with the following quotation:

potential schizophrenics have not broken with reality yet, though they show certain signs of beginning such a break and, under unfavorable circumstances of life, may develop into psychotics, or they are persons who have "channelized" their schizophrenic disposition, eccentrics who are crazy in one more or less circumscribed area and otherwise retain normal contact with reality. One might also question the terms "partial delusions," "partial hallucinations" and "partial stereotypes."

Aside from the perilous trip through the schizophrenic channel in which many workers have floundered, Dr. Fenichel's book is praiseworthy in all respects. The avoidance of numerous references to classic and popular dramatic literature is as refreshing as the use of well known English expressions and idioms. This is not an elementary text for popular reading but a real psychoanalytic reference book for the psychiatrist.

Men Without Guns. Text by DeWitt MacKenzie and descriptive captions by Major Clarence Worden, Medical Department, United States Army. With a foreword by Major General Norman T. Kirk, surgeon general of the United States Army. 8th, cloth, 152 pp., with 137 plates. Philadelphia: Blackston Company, 1945. \$5.00.

This book is based on the work of twelve distinguished artists who were assigned to theaters of action in Europe, the Pacific, the India, Burma and China front and hospitals at home and abroad, training centers and industrial plants in the United States. The artists did their sketches and paintings on the spot. Among the subjects dealt with are the training of physicians and enlisted corpsmen, the production of medical and surgical supplies, the movement of men and supplies in combat areas, the general hospitals, including surgery, convalescence, rehabilitation and occupational therapy, the Army Nurse, the hospital ship, aviation medicine and the performance of the Medical Corps in actual combat zones. Although the artists who went to the front were in actual combat zones and were exposed to diseases of all kinds, none were injured or became ill. The humorous side is not neglected, serving as a bold relief to the serious care of the wounded and ill.

Most of the reproductions are in color and are excellent. The descriptive text is well written in an easy, narrative style and covers the Southwest Pacific, Saipan, Italy, D-Day in Normandy and the Burma Road. This work is an out-

standing graphic contribution to the medical history of World War II and should be in all libraries, public and medical

Science and Scientists in the Netherlands Indies Edited by Pieter Honig, Ph D, and Frans Verdoorn, Ph D 4^o, cloth, 491 pp., with 134 illustrations New York Board for the Netherlands Indies, Surinam and Curaçao, 1945 \$4 00

This collective work, in which the science of the Netherlands Indies is discussed by a number of authorities in special fields, contains some material of medical interest. Five chapters are devoted to the history of the cultivation of cinchona. There are short chapters on veterinary service, beriberi, rabies, medical research, medical education and missionary physicians and hospitals. The larger part of the text is devoted to the natural sciences and chemistry. A valuable compilation of scientific institutions, societies and research workers in the Netherlands Indies will be found in a supplement. A few contributions are written in French and German.

The work is not well arranged from the point of view of subject relation. The text is printed in two columns, and the book is too heavy for its size owing to the weight of the coated paper not required for the kind of illustrations used in the text. The type is much too small for comfortable reading. A lighter paper and larger type, although increasing the number of pages, would have produced a lighter and much more satisfactory volume. The work is valuable, however, in providing a story of science in the Netherlands Indies.

Pathology in Surgery By N Chandler Foot, M D 4^o, cloth, 511 pp., with 368 illustrations and 10 plates Philadelphia J B Lippincott Company, 1945 \$10 00

Dr Foot has written a short book on his personal experiences as a surgical pathologist. Informality in a scientific text is unusual, but it makes the book more readable. It would be almost impossible to cover the entire field of surgical pathology in less than five hundred pages that include almost four hundred illustrations, but the author has tried to do this and in addition has considered many medical conditions in which biopsies are occasionally performed, with the result that he does not do justice to some of the more important surgical lesions. For example, there is no need to spend an entire page on chronic glomerulonephritis and nephrosclerosis. Anyone interested in this subject would naturally consult a textbook on general pathology.

The title implies an exposition on the pathology seen at the operating table. In fact, the fly leaf of the book states, "It is a thorough coverage of the close relationship between the pathologist and the surgeon in the operating room." Unfortunately, the book does not emphasize this aspect because it seriously neglects gross pathology, gross descriptions of pathologic lesions, by and large, being skipped over hurriedly. This might be excused if sufficient gross illustrations were used, but of the three hundred and sixty-eight illustrations, there are only four black-and-white photographs of gross specimens and six color plates, each containing only a few colored drawings of some of the most frequent pathologic lesions, such as appendicitis, cholecystitis and cancer and cysts of the breast.

The competent surgical pathologist is the one who is able to make a diagnosis grossly in the operating room. For example, the most frequent lesion for which the pathologist is called to the operating room is a lump in the breast. The author states, in relation to tumors of the breast, that the surgeon should "cut down upon the tumor and remove a generous biopsy (if not the entire growth)" rather "than to putter with aspiration biopsies." He continues "Should the freezing microtome produce sections that reveal cancer, the operation for radical mastectomy should then be undertaken without further delay, should a nonmalignant growth be diagnosed the wound is then closed up forthwith and the patient returned to her bed. Seldom if ever is it necessary to await the examination of permanent sections from paraffin blocks, although once in a great while a frozen section may give clinical evidence that requires further investigation." From this statement it appears that the pathologist should make frozen sections of all tumors of the breast. In the reviewer's experience most pathologists are able to make a gross diagnosis of lesions of the breast in about 90 per cent of

cases, and often when the gross diagnosis is in doubt the frozen section does not help.

The emphasis throughout this book is placed on the microscopic appearance of pathologic lesions, and many of the photomicrographs are excellent. Some are poor, however, and occasionally, as in the chapter on bone marrow, the text describes many cellular details without accompanying photomicrographs.

The chapters on lymph nodes, spleen and skin contain excellent photomicrographs, and the subjects are well presented. With the increase in chest surgery one would have liked to see a fuller presentation of bronchiectasis and the mediastinal tumors. The handling of the pathology of the adrenal tumors is superficial, in contrast to the fuller discussion of their endocrine aspects. The pathology of the uterus and cervix are considered together, and the fact that their clinical, surgical and pathological features are different is not brought out.

The text is well indexed, and a good list of recent references is given at the end of each chapter.

Personality Factors in Counseling By Charles A Curran, Ph D With a preface by Michael J Ready and an introduction by Carl R Rogers 8^o, cloth, 510 pp., with 71 illustrations New York Grune and Stratton, 1945 \$4 00

The introduction and the preface of this book call to the attention of the reader the need for better interpersonal relations and the dangers implicit in the limitations of individual freedom by various autocratic social systems. A tentative promise of changing emotional disturbance into an understanding, contented, maturely deliberative status is given in twenty counseling interviews.

The text, however, without any statement of principles, methods or technics launches into what is termed a typical, nondirective counseling procedure, the author taking it for granted that the reader is aware of the fundamentals. Automatically recorded interviews are then shown to be better than written or memorized interviews. Actually, several other texts on nondirective counseling are required as a preamble to an understanding of this one. About a hundred pages of the text are devoted to a statistical consideration of the responses or statements of one case. Positive statements, indicating improvement, and negative statements, indicating no progress or regression, have been counted by "judges" and arithmetically projected on increasingly complex charts, finally to be treated by chi-square formulations, which are intended to demonstrate that nondirective counseling brought about improvement in an emotional or anxiety-laden condition. The reviewer would like to believe that personality factors, insight into conflicts and certainly expressions of behavioral adjustments could be statistically evaluated. This wish is still unfulfilled after reading this text. One might similarly count the number of times a patient refers to himself in a number of interviews and mathematically derive an "egocentric ratio," which might then be employed in comparative personality studies. The statistical features in this book seemed to be similarly syllogistic.

In studying the content of the illustrative interviews one is impressed by the fact that "the therapist" (the author) merely echoes or paraphrases what "the client" has previously said—returning the expressions in words more meaningful to "the client" and understanding (by inference) the important affective alterations in the course of the therapy. If this is nondirective counseling, it should be as clearly stated as the suggestions or implicit assurances that improvement is noticeable. It is indeed distracting to note the avoidance of the terms "patient" and "illness" in the consideration of what, on the evidence presented, could very well have been neurotic anxiety and other emotional disorders. The lack of mention of any presenting psychosexual conflict would be amazing if the counseling were not maintained on a superficial level.

In spite of the foregoing the reviewer is cognizant of the author's unlimited patience and considerable knowledge of and rapport with the more important human emotional modalities. The author's counseling ability is known to be equaled by that of few people. It would have been more instructive for a man of his caliber to have written a book that abounded with much case material and a description of how nondirective counseling brought about a solution to presenting symptoms. Instead, this is a conglomeration of severely involved statistical formulations with their implications for future personality studies.

The reviewer believes that it is essential to delineate sharply the respective spheres of medical and nonmedical psychotherapeutic efforts. When can "a client" be classified as "a patient"? When does "a counselor" practice psychiatry without a license? Admittedly, even tritely, there is a lack of trained psychiatric personnel. This may not be the reason for the independent undertaking of rather extensive psychotherapy by nonmedical workers. That people take their troubles to anyone with a sympathetic ear has led to popularized concepts of counseling by such personages as Mr. Anthony and his imitators, the listening to troubles being thus made a financial enterprise. The dangers of such popular inclinations should be pointed out, standards planned and licenses issued accordingly.

With all the above in mind, this book can be of interest to statistically minded students of human emotions and behavior. To the average psychiatrist or to allied professional personnel, probably too much effort will be required in reading to make it useful.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Suggested School Health Policies. A charter for school health. Second edition. Revised by the National Committee on School Health Policies of the National Conference for Cooperation in Health Education. 8°, paper, 46 pp. New York and Minneapolis: Health Education Council, 1946. 25 cents.

This pamphlet, which is written as a guide for all concerned in school health, integrates the viewpoints of many professional groups on the contributions that school programs can make for the health of children and communities. The National Committee on School Health Policies consists of fifteen representatives of fifteen different educational, medical, social and public-health organizations. Eight of these organizations are medical in character, and the chairman of the committee is Dr. Charles C. Wilson. The program is an outline of six main divisions, as follows: provisions for healthful school living, health and safety instruction, services for health protection and improvement, health aspects of physical education, education and care of the handicapped, and qualifications of school-health personnel. There is a preliminary chapter on general health policies. The pamphlet includes suggestions for a school program. Appended to the text is a selective source bibliography on the various aspects of the subject. This pamphlet is recommended to all persons concerned with public health in the schools. It should also be in all public-health libraries.

A Malarialogist in Many Lands. By Marshall A. Barber, A.M., Ph.D. With a foreword by Paul F. Russell. 8°, cloth, 158 pp. Lawrence, Kansas: University of Kansas Press, 1946. \$2.50.

In this popular book Dr. Barber informally tells the story of his travels and experiences in the war against malaria. He has been chasing malaria plasmodia and their anopheline vectors for half a century in the United States, Central and South America, Europe and Asia. To Dr. Barber belongs the credit for discovering the effectiveness of Paris green as a larvicide. In conjunction with Justice B. Rice, he improved a cumbersome and laborious precipitin test so that it could be used rapidly and cheaply to determine the source of blood meals of thousands of mosquitoes. This basic work made it feasible to measure on a large scale the amount of contact between Anopheles and man, and thus to focus attention on the one or two species chiefly responsible for spreading malaria in any given region. In conclusion, Dr. Barber states that the amount of malarial illness rivals that of any other disease, except perhaps the common cold. He believes that all dwellings should be screened at night as a protection against the entrance of mosquitoes. A significant aspect of the book is the way in which it shows how the prevalence of malaria is related to environmental factors, such as flood, famine, irrigation and the presence of wild animals. The book is written in an informal, easy style and should find a place in all public and medical libraries.

NOTICES

ANNOUNCEMENTS

Dr. Archie A. Abrams calls attention to the omission of his office address and telephone number from the current telephone directory. His office is at 1093 Beacon Street, Brookline, and the telephone number is ASPinwall 8951.

Dr. Albert H. Covner announces the opening of his office, with practice limited to diseases of the heart, at the Hotel Breakers, 285 Lynn Shore Drive, Lynn.

Dr. W. Philip Giddings announces the opening of an office for the practice of general surgery at 266 Beacon Street, Boston.

Dr. Harry Portman announces his return from military service and the opening of his office for the practice of medicine at 769 Salem Street, Malden.

HOSPITAL RESEARCH COUNCIL

A meeting of the Hospital Research Council will be held in the Bigelow Amphitheater of the White Building, Massachusetts General Hospital, on Tuesday, February 25, at 4:30 p.m.

PROGRAM

Competition of Antitoxin and Lecithin for *Clostridium welchii* lecithinase. Drs. P. Zamecnik and F. Lipmann.

The Effect of Oral Streptomycin on the Intestinal Flora. Dr. L. W. Kane.

Disseminated Encephalomyelitis Experimentally Produced by the Use of Homologous Antigen. Dr. L. Raymond Morrison.

The Excretion of 11-oxy corticosteroid-like Substances by Normal and Abnormal Subjects. Drs. N. B. Talbot and F. Albright.

TUFTS MEDICAL ALUMNI ASSOCIATION

The annual medical alumni lecture will be presented at Tufts College Medical School on Wednesday, March 5, at 4:00 p.m. Dr. Curtiss B. Hickcox, professor and head of the Department of Anesthesiology, Temple University School of Medicine, will speak on the subject, "Development of Anesthesiology and Its Relation to Medicine in General."

AMERICAN CHEMICAL SOCIETY

A symposium "Antibiotics," with Dr. Chester S. Keefer serving as chairman, is included in the program of the coming meeting of the Northeastern Section of the American Chemical Society. This particular exercise will be held in Room 10-250, Massachusetts Institute of Technology, at 4:05 p.m. on Thursday, March 13. The first paper, "The Role of Antibiotics in Medicine," will be given by Dr. Keefer, the second, "Penicillin Chemistry and synthetic approaches," by John T. Sheehan of the Massachusetts Institute of Technology, and the third, "The Discovery and Development of Streptomycin," by Selman A. Waksman, of Rutgers University. A general discussion and questions will follow.

AMERICAN SOCIETY FOR THE STUDY OF STERILITY

The third annual convention of the American Society for the Study of Sterility will be held at the Hotel Strand, Atlantic City, New Jersey, on June 7 and 8, 1947. The general theme of the meetings will be that of attempting to disseminate to the physician treating marital infertility an overall picture of the latest advances in reproduction. The convention will include original papers, round-table discussions, scientific exhibits and demonstrations. Registration for the sessions is open to members of the medical and allied professions. Additional information may be obtained from the secretary, Dr. John O. Haman, 490 Post Street, San Francisco 2.

THE PHYSICIAN AND SCHOOL MEDICAL SERVICES

GEORGE M. WHEATLEY, M.D.*

NEW YORK CITY

THE participation of the United States in war brings, as an almost inevitable aftermath, a wave of popular interest in the health of the school child. After the Civil War, California passed legislation requiring the promotion of physical activities in all schools, and after World War I, many states enacted laws pertaining to medical examinations as well as to physical education. Today, stimulated by the Selective Service findings, a strong current of public interest has set in. No less than ten bills relating to school health were introduced in the Seventy-ninth Congress.

Considerable public money is now being spent on the school health program. Is it being spent wisely? The legislation referred to above demands even more expenditure. Health and education authorities charged with the responsibility for these programs need medical advice and guidance to develop effective programs. It is imperative that physicians give their attention to school health. Too frequently, policies have been made without the advice and co-operation of medical authorities.

With school health again on the threshold of further development, it is important to take stock of its assets and liabilities and to suggest ways in which organized medicine can further improve the health of school children.

PRESENT STATUS OF LEGISLATION

At present forty-three states have laws permitting or requiring physical examination of children in school. These laws should be studied in the light of modern knowledge about child health, because many should be modified or even repealed. Some of the statutes are too restrictive—for example, those specifying that no clothing or perhaps only the shirt may be removed, others are too specific—for example, those requiring a medical examination of every child every year by the school doctor and those requiring that the examination be done by one person, such as the teacher, principal or school nurse.

*Assistant vice-president, Metropolitan Life Insurance Company

Thirty-four states have mandatory statutes covering physical education, many of which also need study and modification, there is a great range in requirements, varying from ten minutes a day or one period a week to sixty minutes a day or five hours a week. In forty-five states health instruction is treated in more or less detail in the courses of study. Has a medical committee ever reviewed these questions to determine if up-to-date facts are being taught? In one state, at least, the medical society has appointed a committee for the purpose of reviewing the courses of study with the state education authorities.

The legislation has not been consistent at either the state or the local level so far as the governmental agency responsible for the health service is concerned. In thirty states with laws requiring physical examination, the education department has the responsibility in eleven, the health department in eight and the two jointly in the remainder. On the other hand, from prepared reports by state health departments throughout the country, it appears that in twenty-six states public-health agencies play some role in developing the health service at the state and local level. There is even greater confusion regarding jurisdiction on the local level. In urban centers with populations of 10,000 or more, education authorities usually control the health service, no data for rural areas and for communities with populations under 10,000 are available. Health departments, where they exist, render some service in these sections.

The data on the administration of school health service in urban communities are presented in Table 1. To complete the picture, the type of service rendered, the agency responsible and the amount being spent in rural areas must be known. More than half the school children in this country live in communities with populations of 2500 or less. The current nationwide study of child health services of the American Academy of Pediatrics¹ will no doubt supply information on this point. State and local medical societies however, can take steps to review

their local regulations to determine if it is necessary to repeal, modify or reinterpret any statute pertaining to school health with a view to improving the quality of medical services and bringing up-to-date health instruction to the schools

How much has been accomplished in the health of the child of school age? Since World War I, immunization against smallpox and diphtheria has become a standard practice by family physicians as well as by schools and public-health services. The science of nutrition has had widespread application

to these children. The legislation relating to medical inspections in schools has undoubtedly placed many children in the hands of physicians for treatment that otherwise might not have been received. Health education through physicians and nurses and through other channels, including the schools, has brought knowledge about available health protection to many homes. The application of this knowledge is reflected in the spectacular decrease in mortality rate among children five to nineteen years of age (Table 2). The decrease in the total death rate was 64 per cent in the group five to nine years of age, 59 per cent for children ten to fourteen years of age

TABLE 2 Death Rates from All Causes among School Children *

and 55 per cent for those fifteen to nineteen years of age. Tables 3 and 4 demonstrate the decline in some of the principal causes of death. Automobile accidents in the group fifteen to nineteen years of age, as might be expected, constituted the only cause that registered a percentage increase.

These accomplishments are the result, in part at least, of better child care administered by family physicians and parents, but school nurses and physicians and teachers have made some contribution,

although an immeasurable one, through their teaching and alertness to the signs of illness and through periodic medical inspection. In spite of this undeniable improvement, certain aspects of school

health service should be strengthened if the advance in child health is to continue.

In localities where such services exist, there is frequently inadequate quality of medical service in the school, and relations with the practicing physicians and other treatment resources in the community are poor. There has also been lack of co-operation between the education and public-health agencies in the community, and the health services in the school have not been planned to provide a satisfactory learning experience for the children.

The following points are essential to the improvement of school medical service: co-operation between education and public-health authorities, provision for health services in the school that are satisfactory learning experiences for children, properly qualified school health personnel and the development and strengthening of relations with the medical profession. Obviously, these four factors do not com-

prise all the elements of the school health program. For a comprehensive outline of policies relating to the entire matter, the Committee on School Health Policies of the National Conference for Co-opera-

tion in Health Education² has recently published recommendations that every physician should read

CO-OPERATION BETWEEN EDUCATION AND PUBLIC HEALTH

Too often, educational and health authorities have been at odds over the responsibility for running the program of school health. Health departments in nearly every state are involved, but so are education departments. Whatever service is rendered by health departments to children while they are in school involves the school administration. The schools include about one fifth of the total community population, and everyone has had contact with the schools. It is the only agency employing trained educators in the ratio of 1:40 in the population reached. Moreover, it is another avenue to the home. On the other hand, the public-health department knows the health problems, the health facts and the health resources of the community.

A growing number of health officers and school administrators are discovering the help that they can be to each other. In some places the two departments, with the aid of other interested groups such as the medical society, have developed a statement of policy to cover school health work. The recommendations of the Committee on School Health Policies,³ referred to above, were an outgrowth of a state committee that the Connecticut State Medical Society helped to initiate. Some states have made formal arrangements to continue this co-operation by establishing a joint committee or council of state and school health. A recent inquiry sent to health and education departments in the United States revealed that practically all the states have some machinery for co-operation between the two departments and that twenty-seven have formal plans for such co-operation. The war appears to have been a factor in stimulating closer working relations between the departments — just as it has between nations. Such a union cannot be dispensed with, any more than that of the nations can.

MAKING MEDICAL SERVICE A LEARNING EXPERIENCE

The two prime purposes of school-health services are to reveal health problems and thereby to call the child to the attention of his physician for treatment, and to create in the child and the parents understanding and desire for preventive medical service.

Medical examination in schools — as performed annually or routinely — has been severely criticized both as a costly and inaccurate case-finding method and as an unfortunate educational experience. Since educators and pediatricians realize that medical procedures in schools have educational implications, the trend is toward fewer but more thorough medical examinations for individual pupils. The value of

the presence of the parent at the examination, especially of younger children, in terms of health education as well as treatment, has been demonstrated, 25 per cent more children received medical care when the parent was present than when the parent was absent. The school physician, in appraising the health status of the child, should utilize information based not only on the physical examination but also on the interview with the parent and, frequently, with the school nurse, teachers and other members of the school staff. The school examination should include a conference with the parent of the young child and with the older child himself, to review the findings, to plan care, to give personal health guidance and to interpret the child's health needs.

That this goal has not been attained may be surmised from the comments of high-school students on their medical examinations in the school. "The whole impression you get," said one boy, "is that it [the medical examination] is something that applies to gym and that all they want to do [meaning the school authorities and physicians] is be sure that you can stand up long enough to get through it." Another student remarked "There are questions we should like to ask the doctor, but he is always in such a hurry." "The school doctors don't examine you all over," another youngster complained, "they take a look at your eyes and, if you happen to have a sore throat, they tell you to get your tonsils out." Other children stated that the schools should provide doctors who are interested and doctors who like their profession. Obviously, these students found the medical examination a superficial, hasty procedure conducted by a physician who did not ask questions about health, in spite of the fact that the medical profession has long maintained that the school medical examination is the most "teachable moment" — the best educational opportunity that exists in the schools.

PREPARATION OF PERSONNEL

The medical examination of school children is usually performed by a part-time physician — a local practitioner, as a rule — who is poorly paid for this work and who is usually given no opportunity for special preparation for it. If the average school physician has received instruction regarding his task, it usually concerns fulfilling the letter of the law. When the law requires annual, biannual or routine examinations, the physicians are put under pressure to do them as rapidly as possible. This results in fifteen, twenty or even sixty examinations an hour, with the result that the medical findings are often valueless. For example, the recent study of findings among the Massachusetts high-school students in 1941, as reported by Southworth, Laumer and Turner⁴ shows a tremendous difference in the defects found among pupils in various schools. Postural defects range from 1 to 80 per cent, dental ab-

normalities from 5 to 79 per cent, visual deficiencies from 0.9 to 36 per cent and cardiac anomalies from 0.3 to 9 per cent. Whereas some difference between schools and communities is to be expected, the variation is so great as to place the validity of the findings in doubt. Physicians have a responsibility to help to improve the quality of health examinations in schools.

Education of the School Physician

An extremely significant development regarding improvement in school health examinations is the publication by the American Public Health Association of a statement on the training and qualifications of school physicians. This report emphasizes the value of experience and instruction in pediatrics and education. The position of a school physician requires specialized public-health training, as well as a knowledge of the characteristics and behavior of normal and diseased children.

At the University of Michigan, a scholarship was recently established whereby a physician serves as assistant resident and resident in the Department of Pediatrics for twenty-four months. He also takes courses in the School of Public Health, after which he serves for at least a year as a full-time school physician at an annual salary of \$6000. It is hoped that this may influence some physicians to enter the field of school health administration as a career.

The bulk of the preparation of school physicians is of necessity on-the-job training. In some communities time is set aside for meetings where the physicians are given instructions in certain aspects of child health and may even be given some understanding of modern education. Physicians welcome the opportunity to learn about school health when they obtain this knowledge from competent authority. State health departments, in co-operation with education departments and the medical societies, can and should help. Regional conferences or institutes can be held, authorities from medical schools, teacher-training institutions and schools of public health being invited to participate.

The administration and continued development of health services along the lines proposed require supervisory personnel. Physicians doing school work need the leadership and guidance that competent medical supervision can give. In most states, except for a few urban communities, this supervision is woefully deficient.

Consultant Service

Some school health programs have developed consultant service for special health problems revealed by the examination. For example, heart disease, which is a relatively frequent and serious finding in children of school age, is difficult to diagnose. Some communities do not permit the removal of clothing, the physician does not have the advantage of fluoro-

scopic or x-ray equipment or other laboratory aids essential to the diagnosis. In New York City, Cincinnati, Rochester and Syracuse, school children are referred by school physicians to a specialist, who has the advantage of more time and laboratory aids for a diagnosis. This service, which is provided with the approval of the medical society, is similar to that provided by health departments for the diagnosis of tuberculosis and some other diseases. By this careful procedure, more accurate diagnosis for a serious condition is assured, and modification of the school program can be based on a clearer understanding of the child's potentialities.

Medical Advisory Functions

Instead of giving all his attention to finding defects, the school physician should be encouraged to develop the guidance aspects of his services. His value to a school should be measured in terms of the advice he gives to the children, parents and teachers with whom he comes in contact. He should assume professional leadership, establishing relations with private physicians and clinics and bringing all community resources into closer connection with the school.

He should help to keep teachers conscious of health. When teachers have been properly informed what to look for in the behavior and appearance of pupils and encouraged to refer children to the physician, 80 per cent of the children will be found to merit his professional services. His work should be co-ordinated with that of the nurse at the time of the examination so that undivided attention is given to each child and parent. He should concentrate his efforts in the examination on the discovery of poor health habits, gaps in the knowledge of parents about health matters, health problems suspected by teachers, defects that obviously hamper learning and medically neglected children. These problems exist at every grade level. The program should be flexible and permit the school physician to be of service to children at any time in any grade.

With the parent present at the examination, with stress on adequate history taking, with emphasis on the interpretation of his findings to parent, nurse and teacher and with careful attention to the planning of aftercare of the child, the school physician can meet his educational opportunities and responsibilities. Under these conditions, his data are adequate, for he has not neglected facts provided by the teacher and the parents that relate to the educational, emotional and social problems of the child. His attitude toward his work will be more confident because he has a clearer understanding of his function in relation to the school and the community. His professional morale will be strengthened because he is giving his best judgment in a variety of ways each day.

THE TEACHER'S ROLE IN HEALTH SERVICE

Nyswander⁴ demonstrated that the teacher's responsibility for observing the health of pupils can be made an effective part of the school health service. Teachers were prepared to observe and report to school nurses the health condition of pupils. The annual medical inspection was replaced by annual and semiannual conferences between the classroom teacher and the school nurse. After teachers had received preparation, eight out of every ten children selected in these conferences, when examined subsequently by the school physician, were found to have a health condition requiring further medical attention. The study also revealed that teachers need more knowledge of and experience in observing health behavior and recognizing health deviations. It should be understood that this preparation of teachers is not for the purpose of assuming work to save the time of nurses and physicians, but primarily to enable the teacher to perform more adequately an important responsibility. The Michigan Superintendent of Schools⁵ has published a helpful guide to aid teachers in the observation of the health of pupils.

In reply to a recent inquiry that I forwarded to state education and health departments regarding teacher participation and observation of the status of the health of pupils, twenty-three out of thirty-six states recognized the value of teacher observation and the need for material, and eleven states had already prepared such material.⁶

MEDICAL RELATIONS

The most important aspect of school health service is that of the medical relation between the school medical service and the facilities for treatment in the community. As pointed out above, the main objective underlying the school health service is to ensure that something is done about children who have adverse health conditions.

With the development of school health work in this country, the case-finding or examination program has been considered the responsibility of the school physician, and treatment that of the community physician. The community physician may work in a clinic or in his own office, the family or community may pay him a fee or the service may be covered by some type of prepayment plan. Regardless of the circumstances governing the method of distributing medical care, what is done for the child depends on the knowledge, interest and skill of the physician, as well as the available resources for diagnosis and treatment. There is a gap between the physician who finds a problem and the physician who solves the problem, the road from the school to the source of treatment has been called the pathway to correction. Efforts to bridge that gap have occupied many millions of hours of

thousands of faithful, earnest nurses, many of whom were guided by little or no direction or information. Frequently, the family never had any clear concept of its responsibility. And when the gap seemed bridged and the child was taken to a physician for further examination, the school's diagnosis was wrong or rejected, or no treatment or improper or inadequate treatment was given.

The school can be of aid in improving medical relations by developing in those who provide the treatment understanding and co-operation regarding the case-finding work in the schools. Many practitioners are indifferent to or perhaps hostile to its aims. I have known such physicians who regarded the school health service as meddling with their patients. I have observed that mutual interest in the health of the child is usually a common ground for understanding. When the practitioner understands that health service can aid him both in diagnosis and in follow-up study, as well as treatment in special circumstances, he becomes the essential link in the chain of health care for the child. Practitioners in the community need to be kept informed of school health practices through their meetings, bulletins and so forth.

The school must also create confidence on the part of the practitioner in the school's medical findings, which the physician often mistrusts. He has had children referred by the school for treatment when he has already advised the family, on the basis of previous knowledge and observation of the child, that such treatment was not necessary. In individual cases, the remedy lies in informing the practitioner of the circumstances behind the referral. For example, in a case of diseased tonsils, the family physicians may not have seen the child for a year or more, although the child may have been sent home by the school nurse with acute tonsillitis on more than one occasion during this period. If the school puts this information in the referral note to the practitioner, his diagnosis and treatment may be influenced.

Pediatric and other consultative services should be provided for the physician. Many of the conditions in school children requiring treatment call for special professional skill — for example, dental care, visual and hearing defects, and rheumatic fever and rheumatic heart disease. This is particularly true in rural areas, where specialists in these fields are often not available. The element of higher costs is also involved in the treatment of these conditions.

The development of methods based on these principles would improve medical relations with the physician, in both the office and the clinic, concerning what goes on in the school, how the school health service functions and what the health needs of children are and, most important, would encourage the use of all the modern facilities for diagnosis and treatment. The attainment of this

end calls for special training of school physicians and nurses to aid them in their work with individual physicians in the community

Another principle, which is a logical development at this point, is the greater participation of the community physician in case-finding and in the medical examination. The gap between finding the case and obtaining treatment was mentioned above, and some ways of bridging it have been suggested. Another means is to have the school examination done by the community physician. Many school systems have rejected this idea—some on the grounds that if the outside physician is encouraged to participate, the school physician will not have a job, and others on the basis that examination by the former is not so carefully done as that done by the latter. But many children have had some medical attention prior to entering school. Therefore, the family should be encouraged to employ the physician to whom the child may already be accustomed and who, under these circumstances, may know far more about the child's health than the school physician is likely to learn from the brief contact with the child in school. If treatment is needed, the child is already at the treatment agency, and time would be saved in follow-up examination. Furthermore, if the physician carries a part of the responsibility for examination, the school physician will be released for further advisory service to principals and teachers in the schools.

* * *

Medical understanding and leadership are needed in the school health program. This is recognized by some state medical societies, one of which has encouraged county medical societies to name committees on school health, with the result that committees have been formed in forty-four out of sixty-one counties within the last two years. Recently, the Massachusetts Medical Society named a committee to study the ways and means of improving the school medical services.

Although school health has advanced from the earlier days when it was mainly concerned with the control of contagious diseases, there is a great deal of room for improvement. State laws are in many

respects outmoded. The quality of the medical service in the schools is often of a low order. Co-operation between health and education departments should be encouraged, and there should be a much closer working relation between the school and the practicing physicians in the community. A committee of a medical society might initiate specific activities to improve the quality of the school medical service. A program of teaching sessions, institutes or seminars should be planned in co-operation with health and education departments to refresh school physicians about child growth and development and other medical problems of children—especially nose and throat conditions, allergy, endocrinology, rheumatic fever and mental health. Standards of qualifications for school medical personnel should be developed and employed. A statement on the type of medical examinations to be done in the schools should be drawn up. If necessary, repeal, modification or reinterpretation of state laws to permit proper medical examinations in the schools should be obtained. Finally, adequate remuneration for the services of the school physician should be guaranteed.

The improvement of all service for children cannot take place without thorough understanding of current programs. If the health of children is to be safeguarded and necessary treatment given, planning of programs must be done in co-operation with educational and medical authorities in the community. Mistakes in school health programs are thereby less likely to be repeated, and some may even be rectified. Certainly, in this way, adequate health care and supervision of school children is likely to be achieved.

PHYSICAL REHABILITATION OF DISABLED PERSONS*

GEORGE G. DEAVER, M.D.†

NEW YORK CITY

THE following statement of the purposes of rehabilitation programs¹ provides an excellent analysis of the co-operation of all groups that will be necessary

The goal of any rehabilitation program is to achieve the maximum function and adjustment of the individual and to prepare him physically, mentally, socially and vocationally for the fullest possible life compatible with his abilities and disabilities

In the establishment of any rehabilitation project it must be realized that industry is the keystone in the whole structure because industry must take the finished product and, by careful and selective placement, utilize these individuals within their capabilities. Labor must understand that the third phase of medical care — rehabilitation — is a service and right that must be made available to all citizens in a democracy and that they have a right to expect such opportunities. The medical profession, governmental and social agencies, insurance companies, and individuals must be made cognizant of the opportunities available in a comprehensive, well-rounded program of rehabilitation and that with such a program, handicapped individuals may be transformed from dependent invalids into contributing, self-respecting, self-supporting citizens.

Every social minded person will agree with these conclusions, and one of the greatest problems that the Nation faces today is the rehabilitation of the physically, emotionally and economically disabled. Eugene J. Taylor,² formerly chief, Education Branch, Convalescent Service Division, Office of the Air Surgeon, has summarized the implications of the question as follows

We had in America prior to the onset of World War II some twenty-three million persons disabled in some degree from disease, accident or earlier wars. Each year there are some 350,000 persons disabled outside of military service. We had in 1940 some six and a half million disabled males between the ages of 15 and 64 years, men who normally would be income-producing. These six and a half million plus the number of disabled or handicapped veterans being discharged from our military hospitals will give us, when demobilization is completed, approximately eight million working-age males who are disabled to the extent of requiring physical or vocational rehabilitation or special placement aids if they are to be adequately employed. This represents one person in sixteen in our general population and one in seven in our male working population.

We have had during four years of war, a total of approximately seventeen thousand amputations in the Army, but we have nearly 120 thousand amputations from disease and accident among our civilian population in that same period. Eleven thousand soldiers were wounded on the beaches of Normandy in the first ten days after "D" Day, yet even with curtailed traffic, automobile accidents alone accounted for more than twice that many civilian casualties in the same ten days.

The problem of the disabled and handicapped is not a new one. War has only focused the microscope of public interest on this great national problem and quickened the necessity for its solution.

The work of the Office of Vocational Rehabilitation has demonstrated how adequate vocational rehabilitation pays

off economically. The 43,997 persons undergoing vocational rehabilitation in 1944 received prior to their rehabilitation an average annual wage of \$148.00. After rehabilitation, the average annual wage of the group jumped to \$1768.00. For the entire group, prior to rehabilitation, the total earnings were \$6,510,556. After rehabilitation the earning power of the same group jumped to \$77,786,696. This gain represents a return of \$47 for every \$1.00 invested.

No amount of money can measure the social and moral satisfaction gained by the successfully rehabilitated and employed handicapped worker and his family. Nor can it measure the value to society of the transformation of these individuals from dependents to productive, self-reliant persons.

A study of the medical aspects of the problem indicates that the medical profession has often failed to contribute its share in attaining the objectives of rehabilitation. Physicians and surgeons have become so interested in the technologic phase of medicine that the humanistic aspect has often been forgotten, they have been so engrossed in treating the disease that the patient has often been forgotten. As a result there is a gap between the present practice of medicine and the needs of the patient. Unless the disabled person is rehabilitated to the fullest possible life compatible with capability, the physician has failed in his duty to the patient.

What are the basic needs of the disabled? In twenty-seven years of experience at the Institute for the Crippled and Disabled, such needs have been found to be the ability to walk and travel, to care for the daily needs and to have the maximum use of the hands. No patient should be discharged from a hospital until he has reached his maximum ability in attaining these three objectives.

The present procedures in a great majority of hospitals deserve consideration. The surgeon amputates the limb. The patient recovers from the operation in good condition, and the stump is all that could be desired. The surgeon is too busy from morning to night in consultation, teaching and operating to be expected to give the time to or become interested in the slow, laborious and protracted third phase of medicine. But someone must apply the bandages to shrink the stump, exercise what remains of the limb, prevent contractures, teach the patient how to use crutches and recommend the proper type of prosthesis. Many months later, the patient must be taught how to use his artificial limb in walking, climbing stairs, sitting down and arising from chairs, getting into or out of a bus or car and all the other activities necessary for daily living and working.

A prominent surgeon had a cerebral hemorrhage that resulted in a right hemiplegia. He asked his medical and surgical friends for assistance, and they all told him he had hemiplegia following a cerebral

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 23, 1946.

†Clinical professor of medicine, New York University College of Medicine; medical director, Institute for the Crippled and Disabled.

hemorrhage "I know that," he said, "but what can you do to help me?" His desire was to learn how to walk, to care for his daily needs and to have the maximum use of his hands so that he could return to his practice of medicine. The morale of these patients quickly rises when they are taught to walk with a crutch or cane, to lace their shoes and tie a bow with one hand, to cut their own meat with a special knife, and to learn left-handed writing and the many other activities necessary for self-care.

Massage, electricity and exercise are useful forms of treatment, but functional activities to meet the needs of the patient have more basic therapeutic value because they lead to independence. Better results are obtained by working *with* the patient than by working *on* him.

More than a thousand soldiers, and many times that number of civilians, have a loss of motion and sensation of the lower extremities with incontinence, as a result of spinal-cord lesions. By proper rehabilitation procedures every one of these patients with a dorsal or lumbar lesion can learn to travel with braces and crutches and to care for his daily needs and can be trained in a useful vocation.³

The procedures for meeting the needs of the patient are a function of specialists in physical medicine. A recognition of the needs of the patient and the sources from which they may obtain help will aid physicians and surgeons to restore their patients to the maximum capacity.

The six principal groups of seriously disabled patients needing rehabilitation are the blind and partially seeing, the deaf and hard of hearing, the cardiac, the tuberculous, the neuropsychotic and those generally classified as orthopedic. The restoration of the person with a so-called "one-organ" or "special-organ" disability is not such a difficult problem, because only one organ is involved. The blind cannot see, the deaf cannot hear and the cardiac and tuberculous patients need guidance on the amount of work they can perform. Rehabilitation is infinitely complex in the neurotic and psychotic patients because of the influence of the mind on the body and the intangible intricacies thereof. Not much less difficult, however, is the rehabilitation of the orthopedically disabled because of the great variety of conditions that may occur. When one considers the hundreds of muscles, bones, ligaments and joints and the vast network of blood vessels and nerves supplying the extremities, the number of possible disabilities is impressive.

* * *

Rehabilitation begins on the day when definitive medical treatment is no longer required. The procedures that have been found most successful in Bellevue Hospital are as follows.

Consultation

When the physician or surgeon decides that medical or surgical treatment is no longer needed, the

physician in charge of physical medicine is called in consultation. No patient is accepted for treatment without a consultation. On the department referral form are recorded the patient's name, age, sex and vocation, the date of onset of the condition and the date of admission to the hospital. The intern or resident gives all the information concerning the patient and the re-establishment of function that is indicated. From this information the etiology, diagnosis and results desired are recorded.

If the patient is referred from the outpatient department, the information is obtained from the hospital records and the physician's referral form.

Physical Examination

The purpose of the physical examination is to obtain data concerning the disability resulting from the injury or disease, the extent of the disability and the handicap produced by the disability.

The disability The so-called "orthopedic disabilities" caused by congenital defects, disease or trauma affect the proper functioning of bones, muscles, joints, ligaments, brain and nervous system and produce disabilities limiting movement of the joints or action of the muscles. Fractures, tuberculosis and osteomyelitis of bones, arthritis of the joints, the dystrophies of muscle, sprains and dislocations produced by injuries to ligaments, cerebral palsy, brain trauma, poliomyelitis, multiple sclerosis and transverse myelitis that affect the brain and spinal cord produce disabilities that result in decreased motion or loss of motion at the joints or changes in the normal strength of muscles, or both. It is the physician's responsibility to record the disability, since rehabilitation is concerned with the incapacity and not with the diagnosis.

Extent of disability It is impossible to evaluate the results of treatment unless the extent of disability is recorded. This information is obtained for the physician by physical therapists who are trained in these procedures. The method of measuring and recording limitations of motion can be illustrated by the following case. A patient fractured the radius by falling on the ice. The fracture had healed, and rehabilitation procedures were indicated because of a flexion deformity at the elbow. The record of the physician disclosed that the cause was trauma, the diagnosis, a fracture of the radius and the disability, limitation of motion at the elbow joint. The extent of the limitation of motion had to be ascertained. The normal range of motion at the elbow is from 180° in extension to 35° in flexion. The therapist measured the range of motion with the goniometer and recorded the extent of disability as 140° in extension and 60° in flexion. This indicated that the patient needed 40° more motion in extension and 25° in flexion.

By this method of recording the limitation of motion, the physician can determine at a glance the extent of the disability. It is also possible to evaluate

the results of treatment by having the therapist remeasure the motion in the joint and record the findings on the chart each week.

When the disability produces muscular weakness it is necessary to evaluate the extent of disability by testing the muscular power of the parts of the body affected. The therapists have been trained to evaluate muscle power and the findings are recorded in the following manner. A patient with a "dropped foot" following poliomyelitis has a disability consisting of flaccid paralysis of the leg and foot, the extent of the disability being a trace of dorsal flexion, normal plantar flexion, poor inversion and good eversion. It is only when the strength of a given group of muscles producing a movement is known that the danger of overworking weak muscle groups may be prevented, the proper remedial exercises prescribed and the treatment evaluated. Muscle strength can be further evaluated by giving each of the twelve degrees of muscle strength a unit value of one — these are referred to as "units of motor function."

The handicap produced by the disability The purpose of any treatment is to prepare the patient to meet the physical demands of daily living and working. It is impossible to determine from the measurements of joint motion and strength the ability of a person to perform functional activities. The only method of evaluating such ability is to have the patient perform the activity.

What are the activities necessary for daily living? They have been found to be walking and traveling, caring for daily needs and the maximum use of the hands.

Our test of the physical demands of daily living consists of thirty-seven activities.⁴ The patient travels around the testing area performing each activity as he progresses. He is given instruction on the activity to be tried and the need for the activity in daily living. The activities that cannot be performed are included in the daily program.

* * *

The carrying out of such a program is part of the hospital treatment of every patient. Patients leaving the hospital should be able to walk and travel and care for their daily needs if the gap that exists between the practice of medicine and the needs of the patient is to be bridged. Physicians and surgeons do not have the time or interest to perform this evaluation and rehabilitation program, which should be carried out by specialists in physical medicine. The object cannot be accomplished by heat, light, water, massage or electricity or by weaving and making toys in occupational-therapy shops; it can be attained only by working with patients, showing them their limitations and motivating them to accomplish the activities necessary for daily living.

Before returning to work, a person who has been injured should be tested in the factors necessary for working. After seven years of research the War Manpower Commission⁵ published a book that gives an analysis of physical demands for several thousand vocations in terms of functional activities, such as walking, standing, pushing and lifting. Of the twenty-five activities listed, twenty depend on the movements of the joints and strength of the muscles. Before a disabled person is placed on a job the physician decides which of these physical factors he has partial capacity or no capacity to perform. It is my firm conviction, based on the experience gained from examining thousands of orthopedically disabled persons, that an attempt to predict the physical activities that can be performed by a disabled person on the basis of inspection or even of a muscle test is unscientific and unfair to the patient. No one can predict with any degree of reliability the compensatory ability of a disabled person to perform functional activities until he tests the person in that activity.

We are now developing a test that will indicate the ability to perform these twenty-five activities that the patient can take to his employer when he returns to work. The employer will thus be able to compare the activities essential to the job with the worker's ability to perform them.

* * *

In summary, rehabilitation of the physically disabled requires that definite procedures be followed to attain success. They are a knowledge of the cause, diagnosis and disability, an evaluation of the extent of disability in terms of limitation of motion and strength, an evaluation of what activities, essential to daily living and working, the disabled person can accomplish, and a program that teaches the patient how to achieve the maximum function for the fullest life compatible with his abilities and disabilities.

The accomplishment of these objectives is the function of physical medicine. They cannot all be accomplished in the hospital. In the near future every city will have rehabilitation centers, where patients will be sent after discharge from the hospital, in which the patients will live if they are ambulatory or to which they will report daily as outpatients if they can walk and travel. They will be required to work all day to attain their maximum physical, mental, social and vocational rehabilitation and adjustment. Such centers will enable a disabled person to retain his self-respect and become self-supporting. Industrial firms will save pensions. Labor will save a valuable workman. The Government will have another taxpayer. Relief rolls will be reduced. Thus, the third phase of medical care will be developed, and the gap that

exists between the practice of medicine and the needs of the patient will be bridged

A COMPARATIVE STUDY OF PENICILLINS X AND G AND CRYSTALLINE PENICILLIN G*

GEORGINE ROTMAN-KAVKA, M D,† HAROLD L HIRSH, M D,‡ AND HARRY F DOWLING, M D§

WASHINGTON, D C

FOUR different fractions obtained from the mold *Penicillium notatum* have been identified. These have been named penicilins F, G, K and X.¹ The two that have received the greatest attention are the G and X fractions. Many commercial preparations containing varying percentages of these two fractions have been employed clinically with little attention to the actual composition of each product. This practice seems to be justified if studies of these two fractions reveal no significant differences in their properties, but is not justified if either is found to be superior. Accordingly, a study comparing the absorption, excretion, therapeutic activity and toxicity of penicillin G and penicillin X, and the in vitro sensitivity of various bacteria to these fractions was undertaken. For this purpose, the following preparations were employed: commercial penicillin, which contained at least 90 per cent of penicillin G, crystalline penicillin G|| and penicillin X,|| consisting of 75 to 95 per cent of the active substance. Since there were no differences in the results obtained with the various penicillin X preparations, they are all referred to below as penicillin X. Commercial penicillin has been interchangeably called plain, regular, and ordinary penicillin and penicillin G.

Absorption and Excretion

Figures 1, 2 and 3 demonstrate the median values of the blood concentrations obtained at various time intervals with each preparation. The number of assays from which each of these values was determined varied between three and twenty-one. The blood concentrations obtained following the ad-

ministration of penicillin X were consistently higher, and the duration of bactericidal activity was longer, in comparison with those of commercial penicillin and crystalline penicillin G. No significant differences were observed in the height or the duration of the blood concentrations obtained following the administration of commercial penicillin and crystalline penicillin G.

Excretion studies revealed that when 100,000 units of penicillin G and penicillin X were administered intramuscularly, the former was found in the urine for eighteen hours, whereas the latter was present for at least twenty-four hours. The amounts recovered in the urine were 75 per cent of the penicillin G and 55 per cent of the penicillin X.

These observations agree essentially with those of other investigators. Ory et al.² found that the blood concentrations after the administration of penicillin X were significantly higher and more prolonged than those after the intramuscular injection of the same number of units of regular penicillin. Likewise, Welch and his co-workers³ noted that after the administration of 25,000 units of penicillin X and of regular penicillin the former product consistently maintained a higher blood concentration after two hours, and that the percentage of penicillin X recovered in the urine was smaller than that of penicillin G. Meads and his associates⁴ observed, however, that regular penicillin when administered orally yielded higher and more prolonged blood concentrations than penicillin X given by the same route, and they concluded that ordinary penicillin is less readily absorbed and excreted. No other reports on the absorption and excretion of crystalline penicillin G have been published.

In Vitro Sensitivity

One hundred and one strains of various bacteria, including staphylococci, streptococci, pneumococci, gonococci, meningococci and the influenza bacillus, were tested for sensitivity to penicillin X and to crystalline and commercial G fractions. The results of this study have been reported elsewhere.⁵ In brief, it may be stated that no difference was noted

between the two penicillin G products. When the relative sensitivity of penicillins G and X was computed on the basis of weight, it was found that

fraction the organism also became more resistant to the other fraction, although not to the same extent. Similarly, several strains of bacteria that became

FIGURE 1 Median Values of Blood Concentrations Obtained following the Intramuscular Injection of 15,000 Units of Commercial Penicillin, Crystalline Penicillin G and Penicillin X

fifty-five strains were from two to sixteen times more sensitive to penicillin X, twenty-five were equally sensitive to both fractions, and twenty-one were two to four times more sensitive to penicillin G

resistant to fraction G in vivo were also more resistant to fraction X. Welch and his co-workers³ studied the in vitro action of penicillin X and commercial penicillin G

FIGURE 2 Median Values of Blood Concentrations Obtained following the Intramuscular Injection of 25,000 Units of Commercial Penicillin, Crystalline Penicillin G and Penicillin X

Further experiments were performed in which the resistance of various strains of organisms to one of these fractions was increased in vitro. In each instance, when the resistance was raised to one

on several strains of organisms, employing the unit as a measure of comparison. They noted that four strains of *Staphylococcus aureus* were equally sensitive to both fractions, but that one strain of *Kleb-*

exists between the practice of medicine and the needs of the patient will be bridged

No other reports on the absorption and excretion of crystalline penicillin G have been published.

In Vitro Sensitivity

One hundred and one strains of various bacteria, including staphylococci, streptococci, pneumococci, gonococci, meningococci and the influenza bacillus, were tested for sensitivity to penicillin X and to crystalline and commercial G fractions. The results of this study have been reported elsewhere.⁵ In brief, it may be stated that no difference was noted

*From the George Washington Medical Division, Gallinger Municipal Hospital, and the Department of Medicine, George Washington University School of Medicine.

to penicillin X, and that the remaining 50 per cent were either equally sensitive to both fractions or more sensitive to the G fraction. With the exception of a few strains, however, the differences in the sensitivity of the bacteria to either fraction were not great.

Therapeutic Activity

Various infections for which treatment with penicillin has been established were treated with the preparations discussed in an effort to determine whether there were any differences in their therapeutic action. Strict alternation was impossible because of the limited supply, and each product was therefore used when it was available. Table 1 presents the infections and the number of patients treated with each type of penicillin. Some of the cases in which penicillin X was used were discussed in greater detail in an earlier report.⁵ So far as could be determined, the three preparations were equally effective in the treatment of these infections. Although *in vitro* studies revealed certain variations in the sensitivity of the organisms to the types of penicillin, there was no obvious difference in the clinical response, either because the sensitivity of the organisms to each fraction was not varied enough to be of clinical significance or because the concentrations of penicillin obtained with the various regimes employed with all three products were higher than the sensitivity of the organisms, with the result that the lowest concentration was still bactericidal for the causative organism. The evidence available at present indicates that once a bactericidal concentration has been obtained a further increase in the concentration is not of added benefit.

Orv et al.² found that equivalent doses of penicillin X and commercial penicillin were equally effective in the treatment of pneumococcal pneumonia and other infections, such as staphylococcal bacteremia and severe cellulitis. These investigators considered penicillin X more effective than penicillin G in the treatment of gonorrhea when doses of 50,000 to 100,000 units were employed. Welch and his co-workers⁴ reported a 94 per cent cure rate in a group of 68 patients with gonorrhea who were given one dose of 25,000 units of penicillin X, whereas only 64 per cent of a group of 58 patients were cured with the same dose of commercial penicillin. The course of therapy in acute gonococcal urethritis is short, thus, when small doses are given, the prolonged duration of bactericidal activity of penicillin X may account for the observed superiority of this fraction.

There may be two exceptions to the general statement that penicillin X and penicillin G are equally effective therapeutically in all other infections. In the first place penicillin X may be given at less frequent intervals than equivalent doses of penicillin G without loss of the therapeutic effect. Secondly,

an occasional infection may be encountered, in which the causative organism is resistant to penicillin G but is sensitive to penicillin X. In such circumstances the greater sensitivity to penicillin X and the higher concentrations obtained with this product may become significant enough to warrant its use. Flippin and his associates⁹ encountered such a situation in a patient with bacterial endocarditis, who was cured with penicillin X after penicillin G had failed to control the infection.

Toxicity

Toxic reactions to penicillin, such as fever, nausea, vomiting and dermatitis, have been observed. Most investigators report a low incidence, whereas a few state that toxic manifestations are not at all infrequent.^{10, 11} All agree that the reactions are not serious, with few exceptions. The incidence in the series of patients under discussion was low — 7 cases in over 450 patients, almost all the reactions observed occurred in the early days of investigation when the products were impure. Six patients developed urticaria and one a fever. All the patients with urticaria had been treated with the impure commercial penicillin. Five developed symptoms during therapy, and the rash disappeared despite continuation of treatment. The sixth developed a generalized urticaria for forty-eight hours seven days after penicillin therapy had been discontinued. Delayed reactions to penicillin have been reported.^{12, 13} The remaining patient developed a fever while convalescing from pneumonia on the fifth day of treatment with crystalline penicillin G; there was no increase in the severity of the illness, and the temperature returned to normal when penicillin was discontinued. A repeat dose of penicillin did not, however, cause a rise in temperature.

All three products were instilled in the lumbar intrathecal space in the treatment of meningitis. There were no untoward reactions so long as the doses given were less than 100,000 units and the period of injections less than six weeks. Similarly, no unusual reactions were observed following the instillation of these three preparations into other serous cavities.

* * *

A comparison of the properties of penicillin X, crystalline penicillin G and commercial penicillin G demonstrated that penicillin X achieves and maintains higher blood concentrations than the injection of similar amounts of penicillin G, whereas there is no essential difference between the crystalline and commercial penicillin G in this respect.

Most bacteria are more sensitive to penicillin X than to penicillin G, but the difference is slight when they are compared on a weight basis.

The therapeutic effects of all three preparations are similar, with a few exceptions.

The incidence of toxic reactions was low and independent of the type of penicillin employed.

siella pneumoniae and one strain of *Bacillus cereus* were more sensitive to penicillin X, penicillin X was three to five times more effective than commercial penicillin in the protection of mice against ten thousand lethal doses of Type 1 pneumococci

than to commercial penicillin and that most strains of pneumococci and *Streptococcus viridans* were twice as sensitive to penicillin X when the unit was employed as a criterion of comparison. Recently, Hewitt and Pittman⁷ published the results

FIGURE 3 Median Values of Blood Concentrations following the Intramuscular Injection of 50,000 Units of Commercial Penicillin, Crystalline Penicillin G and Penicillin X

Libby and Holmberg⁶ observed that, with the exception of one strain of *Staph aureus* and one strain of *B subtilis*, the strains tested were more sensitive to penicillin X than to penicillin G, but

of a study of the comparison of the in vitro sensitivity of thirty-eight strains of *Haemophilus influenzae* to penicillins X and G. They found that most strains were more sensitive to penicillin X

*Seven patients were treated with doses that were subsequently determined to be inadequate

that the difference was less when the comparison was made on a weight rather than a unit basis. Ory et al² reported that most strains of Group A hemolytic streptococci, gonococci and meningococci were two to eight times more sensitive to penicillin X

and that this fraction was more effective in protecting the laboratory animals against the infection. A tabulation of the results of our studies and those of other investigators reveals that about 50 per cent of the strains of bacteria tested were more sensitive

ptics and to the sulfonamides, and the failure of emicillin therapy and radical sequestrectomy in the previous three-month period

The patients in the 4 cases described below were initially treated by thorough débridement and excision of necrotic tissue and poorly vascularized granulations, as well as by sequestrectomy or saucerization under Pentothal anesthesia. The wounds were, of course, well irrigated with physiologic saline solution. Tourniquets were not used in order that postoperative bleeding and venous stasis might be minimal, thus avoiding dilution of the topically applied streptomycin. In cases in which adequate hemostasis cannot be obtained with hot saline packs at the time of operation, it is far better to pack the wounds with nothing more than vaseline gauze pressure dressings for the first twenty-four or forty-eight hours before streptomycin therapy is begun. On the third or fourth postoperative day, the patient is returned to the operating room, where usually, without anesthesia, the wound can be gently irrigated with hot saline solution and the entire wound bed exposed without further ooze or active bleeding. Gela foam or fibrin foam soaked in streptomycin is then applied to the entire wound surface. The purpose in using gela foam is twofold: to ensure that the entire wound surface is in contact with the streptomycin applied locally, and to promote healing and granulation.

The local dosage of streptomycin was arbitrarily set at about 150,000 units daily, whereas 200,000 units was administered intramuscularly every three hours for patients receiving combined therapy. At present we are treating wounds more grossly infected than those described below with dosages as high as 500,000 units intramuscularly every three hours, and the results have been excellent. Quite often we have observed that *Ps. aeruginosa* is highly resistant to streptomycin both in vivo and in vitro, but this obstacle is easily overcome by the substitution of a 1 per cent acetic acid solution for twenty-four hours. Before further streptomycin therapy is given, the wound should be thoroughly irrigated with saline solution, since streptomycin is rendered inactive in an acid medium.

CASE REPORTS

CASE 1 On February 18, 1944, a 37-year-old private was struck by an automobile while crossing a street in a mid-western state. He was taken to a hospital, where a diagnosis of compound and comminuted complete fractures of the left tibia and fibula, at the junction of the middle and proximal thirds, was made. The left leg was put in plaster from toes to groin after closed reduction of the fracture, following which the general condition was excellent. On March 7 the patient was transferred to a larger hospital, where it was learned that there was about 10 or 15° of posterior bowing of the tibial fracture and about 50 per cent contact between the fracture ends. At that time there was no definite callus formation. Laboratory examinations were essentially negative.

During the stay at the second hospital, the cast was wedged at the fracture site, and posterior and medial angulations were corrected. This change was corroborated by x-ray studies. Immobilization in the plaster cast was continued

until April 26, when the cast was removed and gross motion at the fracture site was observed on physical examination. The denuded skin surfaces about the fracture also remained unhealed. A new long leg cast was applied to the involved extremity, and on July 21 the patient was transferred to the Cushing General Hospital.

At the time of admission there was no clinical evidence of union. Because of the poor condition of the skin of the involved extremity, operation was postponed, and the suppurative skin wounds were treated with sulfadiazine soaks, sulfanilamide powder and penicillin dressings. A sliding type of bone graft was carried out on October 5, but postoperatively the wound broke down and drained copious amounts of thick yellow pus in spite of combined penicillin therapy. On January 2, under intravenous anesthesia, the infected tibial graft was removed, the cavity and surrounding necrotic bone were curetted, and the wound was packed with penicillin-soaked gauze. At that time a large number of colonies of *Ps. aeruginosa* were observed in plate cultures from the wound. In May, since the patient's condition was essentially unchanged, a second sequestrectomy was carried out but drainage continued unabated. In August the wound was sufficiently clean so that it was covered with a dermatome graft, of which 80 per cent took. Subsequent x-ray films, however, showed progressive bone destruction, and on February 5, 1946 a thorough saucerization of the proximal end of the tibia was performed. The postoperative course was stormy; the entire extremity became distended and painful, and the wound drained considerably in spite of Azochloramide dressings. Late in February, sulfanilamide irrigations were initiated with poor results. Acriflavine also proved to be of no value.

In early March culture reports indicated that the predominant organisms in the discharge from the extremity were *Pr. vulgaris* and *Ps. aeruginosa*. In vitro studies showed that the organisms were sensitive to a solution of streptomycin containing 32 units per cubic centimeter. On March 11, under Pentothal anesthesia the defect on the anterior aspect of the left leg was débrided, the skin edges were excised, and the wound was irrigated with physiologic saline solution and then packed with fibrin foam to which 150,000 units of streptomycin had been added. Starting with this date, 200,000 units of streptomycin was administered intramuscularly every 3 hours. In addition to the above therapy the wound was irrigated three times daily with 10 cc of streptomycin, or a total daily equivalent of 150,000 units. Two days later a large amount of autolyzed fibrin foam was removed from the depths of the wound, which was then irrigated with 500 cc of physiologic saline solution. An excellent granulating surface was presented at that time. The entire area, however, was again resurfaced with fibrin foam to which 150,000 units of streptomycin had been added. Local and intramuscular therapy was continued as described above. On the 5th postoperative day local streptomycin therapy was discontinued and irrigation with 1 per cent acetic acid instituted, since the contaminant had become resistant to streptomycin. On the 7th day after operation, under Pentothal anesthesia, the left lower extremity was thoroughly irrigated with physiologic saline solution and a dermatome graft applied to about 90 per cent of the defect. The remaining denuded areas were covered with pinch grafts. Intramuscular doses of streptomycin were continued up to the 7th day following the second operation. The graft was a complete success.

Three months later x-ray films revealed excellent callus formation about the sites of the fractures of the tibia and fibula, and a leg brace was ordered.

CASE 2 On January 30, 1945, a 22-year-old soldier was wounded in action in Germany, sustaining a rifle-bullet wound of the left forearm and a fracture of the left radius, with complete paralysis of the left radial nerve. He was treated at a battalion aid station, where the upper extremity was splinted and dressed, and was subsequently sent to a collecting company, from which he was evacuated to a general hospital. Initially, the wound was débrided, and a plaster cast applied to the forearm. In April because of loss of tissue substance about the middle third of the left radius, a skin flap to the left forearm was carried out, and a Roger-Anderson splint applied to immobilize the bone fragments. Following this procedure the patient was evacuated to the Zone of the Interior.

It is concluded that in practically all infections caused by penicillin-sensitive organisms there is no obvious clinical difference between the effectiveness of the penicillin X and G fractions

TREATMENT OF CHRONIC OSTEOMYELITIS WITH STREPTOMYCIN

A PRELIMINARY REPORT

MAJOR TIMOTHY A LAMPHIER, M C, A U S, * AND CAPTAIN CHARLES CASHMAN, M C, A U S †

FRAMINGHAM, MASSACHUSETTS

AT THE time of this writing no data on streptomycin as a specific agent in the treatment of chronic osteomyelitis had been reported in the literature. The results in the cases reported below are considered sufficiently successful to justify publication.

In World War II a major problem in the treatment of compound comminuted fractures was the resultant chronic infection. There is no doubt that penicillin played a great role in either eradicating or localizing infectious processes. Certainly, the bacteremias and septicemias following compound bone injuries so characteristic of World War I were the exception rather than the rule in World War II. Many soldiers, however, returned to the Zone of the Interior with bone injuries infected with mixed bacteria that failed to respond to penicillin therapy, even though thorough sequestrectomy and débridement had been carried out at overseas installations.

As Abraham and Chain† have aptly stated, the presence of gram-negative bacteria in a wound with mixed infection often inactivates penicillin by the production of the penicillin-inhibiting enzyme penicillinase. Certainly, the majority of gram-negative organisms found in the wounds of patients in the osteomyelitis section of the Cushing General Hospital can be classified as nothing more than secondary contaminants, and as such were not of too great significance from a purely pathological standpoint. In the main, these secondary contaminants

were *Pseudomonas aeruginosa*, *Proteus vulgaris* and *Aerobacter aerogenes*. A careful study of the case histories, however, demonstrated that the organisms markedly prolonged wound healing. The usual local antiseptics, such as Azochloramid, acriflavine and Dakin's solution, which had previously been resorted to when penicillin failed in the treatment of chronic osteomyelitis, were of almost negligible or, at the most, highly questionable value in the so-called "open treatment" of chronic bone infections. One cannot underestimate the presence of pieces of clothing, shell fragments, necrotic tissue and sequestra as causative factors for prolonged drainage with bone injuries. The value of x-ray examination in ruling out the presence of many foreign bodies should not obscure the fact that nonopaque materials, such as small pieces of wood, glass and fragments of clothing, are often responsible for persistent drainage. Rather frequently, sequestra are so small or so obscured by adjacent and viable eburnated bone that they are not detected in routine x-ray plates. Of some value in the location of necrotic material is the placing of probes or the introduction of a contrast medium such as Diodrast in sinus tracts, followed by routine x-ray examination, but even these aids are not applicable in every case.

Prior to treating any cases of bone infection with streptomycin, we have considered the following factors: the predominant type of organisms cultured from the wound, in vitro studies repeated on at least three separate occasions during the week prior to the onset of therapy, the duration of the drainage, the failure of the drainage to respond to local anti-

otics and to the sulfonamides, and the failure of penicillin therapy and radical sequestrectomy in the previous three month period.

The patients in the 4 cases described below were usually treated by thorough débridement and excision of necrotic tissue and poorly vascularized granulations, as well as by sequestrectomy or saucerization under Pentothal anesthesia. The wounds were, of course, well irrigated with physiologic saline solution. Tourniquets were not used in order that postoperative bleeding and venous stasis might be minimal, thus avoiding dilution of the topically applied streptomycin. In cases in which adequate hemostasis cannot be obtained with hot saline packs at the time of operation, it is far better to pack the wounds with nothing more than vaseline gauze pressure dressings for the first twenty-four or forty-eight hours before streptomycin therapy is begun. On the third or fourth postoperative day, the patient is returned to the operating room, where, without anesthesia, the wound can be gently irrigated with hot saline solution and the entire wound bed exposed without further ooze or active bleeding. Gela foam or fibrin foam soaked in streptomycin is then applied to the entire wound surface. The purpose in using gela foam is twofold: to ensure that the entire wound surface is in contact with the streptomycin applied locally, and to promote healing and granulation.

The local dosage of streptomycin was arbitrarily set at about 150,000 units daily, whereas 200,000 units was administered intramuscularly every three hours for patients receiving combined therapy. At present we are treating wounds more grossly infected than those described below with dosages as high as 500,000 units intramuscularly every three hours and the results have been excellent. Quite often we have observed that *Ps. aeruginosa* is highly resistant to streptomycin both in vivo and in vitro, but this obstacle is easily overcome by the substitution of a 1 per cent acetic acid solution for twenty-four hours. Before further streptomycin therapy is given, the wound should be thoroughly irrigated with saline solution, since streptomycin is rendered inactive in an acid medium.

CASE REPORTS

CASE 1 On February 18, 1944, a 37-year-old private was struck by an automobile while crossing a street in a midwestern state. He was taken to a hospital, where a diagnosis of compound and comminuted complete fractures of the left tibia and fibula, at the junction of the middle and proximal thirds, was made. The left leg was put in plaster from toes to groin after closed reduction of the fracture, following which the general condition was excellent. On March 7 the patient was transferred to a larger hospital, where it was learned that there was about 10 or 15° of posterior bowing of the tibia and about 50 per cent contact between the fracture ends. At that time there was no definite callus formation. Laboratory examinations were essentially negative.

TREATMENT OF CHRONIC OSTEOMYELITIS WITH STREPTOMYCIN

A PRELIMINARY REPORT

MAJOR TIMOTHY A. LAMPHIER, M.C., A.U.S.,* AND CAPTAIN CHARLES CASHMAN, M.C., A.U.S.†

FRAMINGHAM, MASSACHUSETTS

AT THE time of this writing no data on streptomycin as a specific agent in the treatment of chronic osteomyelitis had been reported in the literature. The results in the cases reported below are considered sufficiently successful to justify publication.

In World War II a major problem in the treatment of compound comminuted fractures was the resultant chronic infection. There is no doubt that penicillin played a great role in either eradicating or localizing infectious processes. Certainly, the bacteremias and septicemias following compound bone injuries so characteristic of World War I were the exception rather than the rule in World War II. Many soldiers, however, returned to the Zone of the Interior with bone injuries infected with mixed bacteria that failed to respond to penicillin therapy, even though thorough sequestrectomy and débridement had been carried out at overseas installations.

As Abraham and Chain‡ have aptly stated, the presence of gram-negative bacteria in a wound with mixed infection often inactivates penicillin by the production of the penicillin-inhibiting enzyme penicillinase. Certainly, the majority of gram-negative organisms found in the wounds of patients in the osteomyelitis section of the Cushing General Hospital can be classified as nothing more than secondary contaminants, and as such were not of too great significance from a purely pathological standpoint. In the main, these secondary contaminants

were *Pseudomonas aeruginosa*, *Proteus vulgaris* and *Aerobacter aerogenes*. A careful study of the case histories, however, demonstrated that the organism markedly prolonged wound healing. The usual local antiseptics, such as Azochloramid, acriflavin and Dakin's solution, which had previously been resorted to when penicillin failed in the treatment of chronic osteomyelitis, were of almost negligible or at the most, highly questionable value in the so-called "open treatment" of chronic bone infections. One cannot underestimate the presence of pieces of clothing, shell fragments, necrotic tissue and sequestra as causative factors for prolonged drainage with bone injuries. The value of x-ray examination in ruling out the presence of many foreign bodies should not obscure the fact that nonopaque materials, such as small pieces of wood, glass and fragments of clothing, are often responsible for persistent drainage. Rather frequently, sequestra are so small or so obscured by adjacent and viable eburnated bone that they are not detected in routine x-ray plates. Of some value in the location of necrotic material is the placing of probes or the introduction of a contrast medium such as Diodrast in sinus tracts, followed by routine x-ray examination, but even these aids are not applicable in every case.

Prior to treating any cases of bone infection with streptomycin, we have considered the following factors: the predominant type of organisms cultured from the wound, in vitro studies repeated on at least three separate occasions during the week prior to the onset of therapy, the duration of the drainage, the failure of the drainage to respond to local anti-

course was normal, the dressings being removed on the 10th day after operation when the skin graft was found to have taken well. Because of an unstable right ankle joint due to the destruction of many of the tendinous structures in the lower leg, on February 8 an intramedullary sliding type of ankle fusion was carried out on the right leg.

On February 13, following the ankle fusion, x-ray films revealed a sliding bone graft extending from the distal end of the tibia into the astragalus. Other bone detail was obscured by plaster. (During the following month x-ray study showed periosteal elevation along the shaft of the tibia beginning about 5 cm proximal to the distal end of the shaft and extending upward for a distance of 25 cm, associated with the changes were areas of decreased density from the cortex of the tibia that were consistent with bone destruction.)

On February 15 the cast was split because of extreme pain and swelling with cyanosis of the toes. The patient continued to run a moderately elevated temperature, and the wound was therefore inspected, a breakdown of the skin over the lateral malleolus, with purulent serous drainage, was found. Despite irrigation with 1 per cent sulfadiazine solution, the entire anterior aspect of the ankle joint broke down and drained profusely.

On February 20 streptomycin sensitivity reports on organisms cultured from the wound were recorded as follows: *A. aerogenes*, sensitive to 2 units per cubic centimeter, hemolytic *Staphylococcus aureus*, sensitive to 8 units per cubic centimeter, and beta-hemolytic streptococcus, sensitive to 32 units per cubic centimeter. During March, the blood plasma protein was 7.2 gm per 100 cc. Subsequent cultures taken from the wound of the right leg during March were reported as showing *Ps. aeruginosa*, *A. aerogenes*, beta-hemolytic streptococcus and hemolytic *Staph. aureus*. On April 5 the *Ps. aeruginosa* was found to be resistant to 250 units and the hemolytic *Staph. aureus* sensitive to 0.5 units per cubic centimeter of streptomycin. On March 5 daily topical treatment of the wound with 15,000 units of streptomycin was begun. By March 21 the wound had become grossly clean, and the area of the tibia that had previously been exposed was covered with granulation tissue. On March 25 the wound was covered with a split-thickness graft taken from the left thigh, and a vaseline pressure dressing was applied. About 90 per cent of the graft was viable on the 10th postoperative day. During the following weeks a few pinch grafts were used to cover the remaining denuded

areas. Two months later the wound remained well healed. The original fracture of the mid-tibia and fibula had healed without further treatment.

Although the results obtained in these 4 cases were gratifying, it should be emphasized that the evaluation of any method of therapy in cases of chronic osteomyelitis cannot be final until a period of years has elapsed, since in the past there has been recurrence in many cases that have been thought to have been "cured."

Incidentally, the discomfort of repeated injections was successfully alleviated by combining solutions of the drug with procaine.

SUMMARY

Four cases of chronic osteomyelitis are presented 3 of which were treated with combined intramuscular and local streptomycin therapy and 1 with local applications alone. An obvious advantage of the combined therapy is that such procedures as skin grafting and secondary closure can be carried out in a much shorter time. One is easily guided by the success of in vitro studies prior to using streptomycin. No toxic reactions were observed in this series.

On entry to a general hospital, x-ray examination disclosed a 3-cm gap in the proximal portion of the lower half of the left radius. There was a sequestrum adjacent to the proximal end of the distal fragments. No other abnormalities were noted besides the nonunion and marked osteoporosis. Shortly after admission, the sequestrum was removed. On October 1 a bone graft to the left radius was carried out, the left tibia being used as a donor site, but the graft broke down and thick, purulent material started to drain from the anterior aspect of the forearm.

At the time of his admission to the Cushing General Hospital, in January, 1946, the diagnosis was a compound, complete fracture of the left radius, with osteomyelitis and necrosis of the bone graft. On February 8 the bone graft was removed and sinus tracts excised, an indwelling catheter being inserted for subsequent penicillin therapy. In spite of this procedure and subsequent penicillin irrigations, as well as a course of penicillin intramuscularly, two sinus tracts over the volar aspects of the left forearm continued to drain a heavy, thick, purulent material.

Blood studies and urinalyses were within normal limits. On February 14, cultures of the material taken from the draining sinus tracts of the left forearm were reported as showing *Pr. vulgaris*, and the organisms were found to be sensitive to 0.5 units of streptomycin per cubic centimeter. On February 25, under general anesthesia, the sinus tracts of the left forearm were excised, and all necrotic tissue was debrided, hemostasis was obtained, and the wound was packed with fibrin foam soaked in streptomycin. At that time 200,000 units of streptomycin was given intramuscularly, every 3 hours. On the 1st postoperative day local irrigations with 150,000 units of streptomycin were initiated, in addition to the intramuscular therapy. Four days later, since cultures had proved the wound to be clean, a secondary closure was carried out, steel wire being employed as a suture material. Streptomycin continued to be injected intramuscularly (200,000 units every 3 hours) for a total of 7 days, at the end of which the sutures were removed. A few stitch abscesses developed at the periphery of the wound, but these were treated with streptomycin dressings and healed within a 5-day period. The forearm was then encased in plaster and remained well healed for the next 3 months, at the end of which x-ray examination revealed excellent callus formation about the radial bone fragments.

CASE 3 On March 28, 1945, a 21-year-old soldier was wounded in action in Germany, sustaining a penetrating wound of the left hand. Shrapnel entered the dorsum of the hand, fracturing the 2nd and 3rd metacarpal bones, and x-ray films subsequently showed a marked loss of bone substance. The patient was treated in a nearby evacuation hospital, where débridement was carried out, and was then transferred to a general hospital in Paris, where the wound was secondarily closed. On June 14 he was evacuated to the Zone of the Interior, arriving at the Cushing General Hospital on August 13.

On entry, examination of the left hand showed a depressed adherent scar, with a small granulating area in its center, on the dorsal surface over the proximal ends of the 2nd and 3rd metacarpals. The index and middle fingers were about 2 cm short, with obvious bone loss of the corresponding metacarpals. The extensor tendons to the index finger had been destroyed, but that to the middle finger was present. The flexor tendons were functioning normally but through a reduced range because of the adherent scar dorsally, and because of stiffening of the metacarpophalangeal joint secondary to immobilization. The nerves were intact. The diagnosis was a compound, comminuted fracture of the 2nd and 3rd metacarpals, with loss of bone substance.

On August 21 it was decided that, since there was not an appreciable amount of skin over the dorsum of the hand, a small abdominal-flap operation should be carried out, to prepare the finger for lengthening at a later date. On October 11 an abdominal flap was attached to the left hand, and 3 weeks later the flap was detached and inserted.

On January 15, 1946, it was suggested that since the flap on the dorsum of the hand was in good condition, the patient should be transferred to the Hand Section for a metacarpal bone graft. On February 1 the bone graft was carried out, the metacarpal defect of the index finger being filled in and the tibia being utilized as a donor site. Three days postoperatively the patient began to run a septic temperature

and complained of severe pain over the dorsum of the hand. The cast was therefore removed, and the wound was found to be grossly septic. On February 8 cultures of the material draining from the dorsum of the hand were reported as showing *A. aerogenes*, and a few days later these bacteria were found to be sensitive to 0.5 units of streptomycin per cubic centimeter. Since the wound continued to drain profusely in spite of penicillin administered intramuscularly and locally, the ulnar aspect of the abdominal flap on the dorsum of the hand was incised and the surrounding necrotic tissue excised on February 26. The incision was carried down to the dorsum of the bone graft, which appeared to be viable. After thorough irrigation with physiologic saline solution and careful control of excessive bleeding, the wound was packed with fibrin foam soaked in streptomycin. A vaseline dressing was applied to the wound, and the hand was set up in so-called "cock-up position" with the aid of a splint. Post operatively, 50,000 units of streptomycin was injected locally into the wound each day, and 200,000 units was administered intramuscularly every 3 hours. On March 1 specimens were taken from the wound for culture, as well as a small amount of fibrin foam for streptomycin sensitivity tests. Since the wound still appeared to be septic, it was thoroughly irrigated with physiologic saline solution and streptomycin, all remnants of the fibrin foam were removed, and a partial closure was carried out with No. 40 cotton suture, except in the center of the incision, where a small piece of Penrose tubing was placed. Two days later the rubber drain was removed, since the wound appeared to be clean. For a total of 7 days 200,000 units of streptomycin was continued every 3 hours. The skin flap healed rapidly.

Fifteen days later, when the patient was to have a plaster cast applied, the skin flap over the dorsum of the left hand again broke down, draining a small amount of yellow purulent material. Cultures of the drainage were reported as showing *Escherichia coli*, sensitive to 32 units per cubic centimeter of streptomycin, and *A. aerogenes*, sensitive to 4 units per cubic centimeter. Local irrigations consisting of 30,000 units of streptomycin were initiated at once and continued for a period of 10 days, at the end of which the wound had healed spontaneously. Three months later the wound remained closed, and x-ray films revealed excellent callus formation about the metacarpal graft.

CASE 4 On February 7, 1945, a 20-year-old soldier was injured in Werben, Germany, by a land mine, sustaining injuries to the left thigh, leg and foot and to the right buttock, knee, leg, and foot. These injuries included compound and comminuted complete fractures of the right tibia and fibula, as well as paralysis of the right peroneal nerve. The wounds were debrided, and the right lower extremity was splinted at a first-aid station. On arrival at an evacuation hospital, the right leg was encased in a mid-thigh plaster cast, following which the patient was evacuated to the Zone of the Interior and admitted to a general hospital on April 10. At that time a sequestrectomy was performed on the right tibia, but since this procedure did not bring about satisfactory results, a thorough saucerization of the right tibia was carried out early in June. Approximately 3 weeks later, small, deep, pinch grafts were applied to the saucerized area with good results. In September the patient was transferred to the Cushing General Hospital for definitive treatment.

During his confinement, blood and serologic studies and urinalyses were reported as negative. X-ray films of the right lower leg showed a comminuted fracture of the mid-shaft of both bones, with loss of bone substance on the outer anterior surface of the tibia and with numerous, multiple foreign bodies in the soft tissues at the site of the fracture.

In early October the long leg cast on the right lower extremity, in which the patient had been admitted, was bivalved, and a small saucerized area was evident on the anterior aspect of the right leg at the level of the fracture site. At the upper end of the cavity, which was filled with small deep grafts, there was a small draining sinus. Since penicillin dressings were of no avail, on October 22, under intravenous anesthesia, the tibial wound was explored and saucerized, loose bone fragments removed and the area covered with a pressure dressing in which a catheter was incorporated for penicillin instillation. On October 31, under intravenous anesthesia, a dermatome graft was removed from the right thigh and sutured in position over the granulating area of the right tibia. Pressure dressings were applied. The postoperative

short-circuiting in a previously colourful personality certainly is preferable to an incurable psychotic misery

It is generally agreed that the operation leaves the patient with a definite loss of initiative and a shallowness of affect. Other symptoms or tendencies, persistent in a large percentage of cases, include euphoria, procrastination, facetiousness, increased appetite, laziness and tactlessness.⁴ This rather alarming list of characteristics does not, however, prevent many patients from carrying on with work. Berliner et al.⁸ describe a woman, a librarian, who was not able to do simple work in the hospital library a few months after her operation because her powers of retention were greatly impaired. Three months later, however, she took a job in a public library, where she had worked satisfactorily for eighteen months at the time of the report.

Freeman and Watts³ present the following description of the results of leukotomy:

Patients who have made a satisfactory recovery are far from inanimate clods. They are cheerful, friendly, uncomplaining, outspoken, buoyant, for the most part. They fall in with the mood of their companions, are quick to follow suggestions and are not embarrassed, glum or self-conscious. They take an active interest in everything that goes on about them, read the papers, attend movies, work regularly and play games with intelligence and foresight. With them the emotional component of foresight and insight is sufficient for meeting external situations of moderate complexity. Many patients have a more or less complete amnesia for the whole psychotic period.

Hofstatter and his associates⁹ report that, at the time of writing, 14 in a series of 100 patients who underwent leukotomy were regularly employed, 4 of them for the first time in their lives. Another 12 were carrying the full responsibility of house-keeping.

The question of a permanent deficit in intellectual functions following leukotomy has not had thorough study because of the lack, in general, of premorbid data on these capacities in the patients concerned. Hofstatter et al.⁹ state that the intellectual assets were not diminished in their cases. Frank⁷ observes that in a series of 200 cases, except for 16 patients over fifty-five years of age, no impairment of cognition or intellectual deficit was observed a year after the operation. Halstead, Carmichael and Bucy¹⁰ developed a battery of tests designed for assessing the so-called "biologic intelligence." This term, in contrast to the standardized psychometric tests, is explained as follows:

Psychiatry, and for that matter the whole field of biology, has long felt the need for a conception of intelligence more closely related to the clinically observed capacities of the individual for general adaptive behavior.

The tests were given to 8 carefully selected patients before and after prefrontal lobotomy. The guarded conclusions of the authors were that the biologic intelligence, as reflected by an impairment index, did not appear to be altered significantly by prefrontal

lobotomy, and that little is known concerning the behavioral effects of this operation.

The best results from leukotomy are obtained in the long-standing depressions, particularly of the involuntional and agitated types, in obsessive-ruminative-tension states and in certain types of schizophrenia. The more the patient is tense, anxious, emotionally disturbed, the more he is, in effect, fighting his disease, and the better are the chances of relief by this operation. Frank⁷ considers the indications for leukotomy strongest in patients with a colorful personality, beneath whose psychotic symptoms a depth of emotional response can be discerned. The first 75 of his 200 cases were selected exclusively because of distressing and permanently disturbing hallucinations, unmanageable aggressiveness, unceasing melancholic agitation, constant unrelieved anxiety due to delusional experiences or organ sensations. In schizophrenia, the catatonic and paranoid types seem to respond better than the hebephrenic and simplex. Apathy, lack of affect, emotional blunting and paucity of delusional productivity are generally unfavorable indications prognostically, in contrast to tension, overactivity, storminess and richness of delusional material.

It is hardly necessary to remark that organic deterioration of the brain, as in cerebral arteriosclerosis and senile degenerative processes, is a contraindication to leukotomy.

The usual postoperative and convalescent complications in the eventually successful cases are confusion, restlessness, epileptiform convulsions, urinary frequency and incontinence. On the average these clear away within a few weeks to less than a year. The operative mortality is generally reported as being less than 3 per cent.

Social re-education, in the directions of guidance and support, are emphasized by Frank⁷ and by Berliner et al.⁸ as being of critical importance for the postoperative patient. Berliner and his associates regard re-education as especially valuable for patients who have been out of contact with reality for long periods, in whom every effort should be made to prevent a renewal of schizophrenic habits, early discharge is advised only if home conditions are particularly favorable. Frank is not referring only to the schizophrenic invalid in the following statement:

In psychotics who have nobody to look after them outside the hospital or whose families during the many years of illness have lost interest and sympathy for them, or whose environmental circumstances are decidedly unfavourable emotionally or materially, leukotomy is of questionable value. If one neglects the above-mentioned factors, apparently good clinical recoveries will, in the end, be disappointing.

What is considered a successful case? What is meant by "social recovery," "much improved" and "improved"? In general, authors classify patients as socially recovered or much improved if they are able to leave the hospital and to approach at least,

MEDICAL PROGRESS

PSYCHIATRY

VERNON P WILLIAMS, M D *

BOSTON

THE subject of psychiatry is discussed under the headings of leukotomy, shock therapy, neuro-psychiatric disorders in veterans and psychiatric education

LEUKOTOMY

During the past ten years surgical operations have been done on the frontal areas of the human brain in an attempt to relieve psychotic patients, as well as some patients with neurotic reactions, from symptoms that apparently were to be persistent and had not yielded to less drastic forms of treatment

Egas Moniz,¹ in Portugal, was the first surgeon to undertake the operation that is now known as "pre-frontal lobotomy," or "leukotomy," a better term in use in England. Moniz published his first results in 1936. Subsequently, Freeman and Watts^{2,3} developed the procedure in the United States. Briefly, the technical purpose of the operation is to cut the white matter of the frontal regions from its connections with the thalamus — that is, to perform a section of the thalamofrontal pathway. Burr holes are made in both sides of the skull, at a point 3 cm posterior to the lateral rim of the orbit (anterior margin) and 6 cm above the zygomatic process. Through the burr holes a leukotome is introduced, and section of the frontal white matter in both hemispheres is accomplished with this instrument. The cortex is not cut except in a small area for the introduction of the leukotome. The operation is done in the plane of the coronal suture. The technic has been described in detail by Freeman and Watts.³

Why patients benefit at all and to the extent that they do from this heroic operation is still basically a subject for speculation and for further neuro-anatomic and neurophysiologic research. Freeman and Watts³ state

the frontal lobes subserve the functions of foresight and insight, particularly as related to the self. It is in relation to these ego functions that the effective coloring supplied by the thalamus is of overwhelming importance for the adjustment of the individual in his social milieu.

Their theories are given special consideration in a recent monograph⁴ Cobb,⁵ who questions the assumption that the frontal areas of the brain are alone the centers for insight and foresight, presents evidence that leukotomy reduces only quantitatively the neural mechanism for the associative functions.

Whatever the reasons, if the operation is successful, the emotional intensity and coloring of the ideas,

hallucinations or somatic sensations that have plagued the patient subside to an innocuous level, and in some cases the symptoms themselves eventually disappear entirely. In other words, the effect of a successful leukotomy is to take the emotional wind out of the sails of the psychotic process. Severing the thalamofrontal radiations seems to do this. Although the operation is standardized in certain respects, the desired clinical result may depend, in the individual case, on whether the plane of section is precisely in line with the coronal suture or a number of millimeters posterior to it. In this regard, Freeman and Watts³ write as follows:

hypochondriasis and fixation of visceral complaints in involutional depressions have been satisfactorily overcome by a standard operative procedure, but a severe obsessive compulsive neurosis of long duration may require incisions from 5 to 7 mm posterior to the plane of the coronal suture. Long-standing schizophrenia requires the maximum operation. In such cases we usually operate from above, through burr holes 10 to 15 mm behind the coronal suture and 4 cm from the midline.

Another, and most important, point is that the more posterior the plane of section, the less likely it is that the patient will be able to make an even partially adequate social readaptation. Freeman and Watts³ state

in order to obtain satisfactory results sufficient fibers must be severed in order to reduce the emotional component of the psychosis to the point where the ideas no longer dominate the behavior of the patient, yet the incisions must leave sufficient quantities of the frontal lobes in order to permit the patient to make a satisfactory adaptation in a social environment. Every millimeter that the incisions trespass upon the area posterior to the plane of the coronal suture renders this adaptation less complete and more difficult.

On this fundamental issue, these authors were enabled, by multiple operations, to form some opinions, and the search for the ideal plane of section was continued.

In the successful cases, unfortunately, the patient is not benefited to the point of complete cure. If he has lost, or practically lost, his psychosis, he has paid for it with more or less profound changes in his premorbid personality. Kindwall and Cleveland⁶ point out that, although happier and easier to live with, the patient is not so able or complete a person as he was before his illness. Frank⁷ summarizes the situation as follows:

The fundamental personality pattern remains unchanged after leukotomy, it has less legend only. The emotional

*Assistant psychiatrist, Massachusetts General Hospital.

five shocks to a patient almost four months pregnant and ten shocks to one who was seven months pregnant, without premature labor or apparent damage to the mother or the child. Gralnick¹⁵ speculates whether hypoglycemia from insulin treatment caused some maldevelopment in the fetus, resulting in stillbirth.

It seems clear that, to date, there has not been enough experience with this problem to allow any general conclusions. Although Bennett does not state how many pregnant women he has successfully treated, the impression given by the reports discussed above is that electric shock may be a safer therapy than insulin for psychoses during gestation.

NEUROPSYCHIATRIC DISORDERS IN VETERANS

Although insufficient time has passed to approach the perhaps impossible problem of relating military service to the development or continuation of psychiatric disorders in the veterans of World War II, there are a few suggestions that some observers were overly alarmed in predicting a high incidence of maladjustment in the men who were in military service. In a study of 10,000 veterans, said to be representative of the bulk of the Army, Burton, Eaton and McMahan¹⁷ found only 257 men, or 2.57 per cent, who warranted a neuropsychiatric diagnosis. The men had been discharged through a separation center and thus did not include soldiers who were already in hospitals for mental or physical disability. The ages ranged from twenty to thirty-five years. Most of them had been in combat or had been overseas and had had three or more years of service. In what percentage and to what extent, since separation, these men have or will become maladjusted, of course, could not be answered by the authors.

One of their impressions is that the Army Medical Corps has done well in establishing a friendly attitude on the part of the soldier toward psychiatry. "These men no longer feel that only a 'psycho' sees the psychiatrist. From the experience gained here where several hundred thousands of men have been seen, there is no doubt that the psychiatrist has been accepted whole-heartedly." (I trust that this is so and that there can be no substantiation to the passing thought that men about to return to civilian life may well be exuberantly cordial to anybody.)

It has been remarked again and again that difficulty in adaptation to military life does not indicate an inherent incapacity for adjustment to the conditions of a more usual social pattern. In a follow-up study of 6000 men discharged from the Army in 1943 for psychoneurosis, Brill, Tate and Menninger¹⁸ estimated that 86 per cent were working full or part time. Of these men, 75 per cent had seen physicians one or more times since discharge, and

at the time of induction 51 per cent of them had considered their health none too good.

To date, according to most reports in the psychiatric literature, the person of average good integration has withstood the trials and shocks of military service without resultant chronic invalidism from psychiatric causes, and there is no convincing proof that human adaptability is on the wane.

PSYCHIATRIC EDUCATION

Psychiatry is not properly taught in most medical schools, including the best. Through generations of medical students the subject has been considered a questionable branch of medicine, if it was considered long enough to give it even that classification. It certainly did not usually attract anyone except "screw balls," and probably the men who taught it were a little on the "screwball" side. The recent war has changed this estimation to some extent, on the part not only of medical students but also of the public generally. Even before the war psychiatry was considered, in some quarters, with a little less disdain. For some years it has been so interestingly presented at University of Colorado School of Medicine that students have spontaneously taken the elective courses. With the progress of the war, the large number of men rejected from service for neuropsychiatric disability and the considerable incidence of psychiatric disorders among both men in training and men in combat areas drew, as never before, the attention of the medical profession and the public to psychiatry. Many physicians who were not psychiatrists during their service with the armed forces were brought face to face more arrestingly and convincingly than ever in civilian practice with the reality of psychogenic factors in physical disability and symptom formation.

In consequence of this sharper focus and in anticipation of an admitted need or demand on the part of many veterans for psychiatric treatment, a group of prominent psychiatrists, internists and medical educators were brought together in Hershey, Pennsylvania, in February, 1945, by the National Committee for Mental Hygiene and the Commonwealth Fund. A summary of the discussions and the recommendations of this meeting are interestingly presented in a pamphlet.¹⁹

One of the recommendations, in part, was that physicians engaged in the practice of general medicine need education on the neuroses and their care and that an experimental course, or courses, at the postgraduate level should therefore be set up promptly to develop content and methods for such education, the need for a nationwide program, in the light of such experiments, was expressed. A beginning has been made in carrying out this recommendation. For two weeks in April, 1946, twenty-five physicians attended a postgraduate course called

their former social and occupational levels. A full social recovery indicates that, after varying periods of surveillance at home, the patients conduct themselves independently, manage their own affairs and carry on with useful work in a manner that is either comparable with former standards or not necessarily equal to them. Insight into the illness is not included. "Improved" means that the patient may or may not have left the hospital, may do some simple work and is generally much less of a nursing problem than before operation.

In Frank's⁷ series of 200 cases, 84 (42 per cent) were considered social recoveries, and 57 (29 per cent) improved. The types of illness comprised schizophrenia, paraphrenia, paranoia, cyclothymia, involutional depression and chronic obsessional neurosis. The average time of observation, following operation, was fifteen months, and the range was nine months to three years. In the 100 cases reported by Hofstatter et al.,⁹ of 66 schizophrenic patients, 18 were much improved, 24 improved and 20 slightly improved, of 16 manic-depressive patients, 9 were much improved, 4 improved and 3 slightly improved, of 6 psychoneurotic patients, 5 were much improved, and 1 improved. All the patients were studied carefully for at least one year, 37 for more than two years, and 10 for more than three years. Freeman and Watts,¹¹ in a report on 50 schizophrenic patients followed for two to seven years after leukotomy, observed the following results: employed, 16 patients, keeping house, 4, studying or employed part time, 6, at home, 15, and in institutions, 9.

Over-all statistics generally indicate that at least some degree of improvement is the result, for the period of observation, in well over 50 per cent of cases after leukotomy.

From this brief outline of the procedure and application of leukotomy, it is obvious that the operation is one of amelioration, not cure. It should be, and supposedly is, limited to certain patients who are, on the whole, wrecks of human nature. With the patient who is apparently constitutionally subject to manic-depressive reactions of great sweep and intensity, the operation should not be performed until it is as certainly established as possible that periods of remission can no longer be expected. With the adolescent or young person who develops what appears to be a schizophrenic psychosis, the operation should not be done hastily, as though to save him from inevitable deterioration, since there is good evidence that some persons pass through, in biologic development, a span that seems to have the earmarks of a devastating process. On the other hand, although leukotomy is but a few years old, it seems to be the step by which some chronic mental invalids may attain contentment and freedom from harassment that otherwise they could not have.

SHOCK THERAPY

As is well known, insulin coma and electric shock do not provide a permanent cure for psychoses. The value of electric shock in terminating psychotic episodes in the affective disorders, however, is well established. Also, in some forms of schizophrenia, there is evidence that insulin treatment may effect remissions that might not otherwise occur or bring them about sooner and thus shorten the period of hospitalization.

Electric shock is far less effective in schizophrenia than it is in involutional depression and in both the manic and depressed phases of the manic-depressive psychosis. Yet its successful use is reported in acute excitement and catatonia.^{12, 13}

In spite of the most gratifying and striking results in many cases of depression, it is still to be proved that an indefinite number of electric shocks produce no permanent damage to the brain. Bennett¹² states that although there is no conclusive evidence of permanent brain damage, the total number of shocks that may safely be given is not clear. So far as the partial memory defect that, more frequently than not, accompanies a series of shock treatments is concerned, Lewis¹⁴ remarks that some patients do not regain their complete memory after many months and asks if it is possible that some never attain their original faculty.

There are no published data, so far as I know, on the correlation between the permissible number of electric-shock treatments and the probability of a lasting memory defect. It seems that such data could never be accurately collected, since there is a wide variation in original, individual memory capacity. In any event the suffering to be endured by the deeply depressed patient and the danger of suicide, as well as the social, domestic and economic ramifications, justify an initial series of five to fifteen treatments.

An interesting and sometimes important consideration is the development of mental illness during pregnancy. If, for some reason, therapeutic abortion is excluded, should shock therapy be tried? There are few reports in the literature on this question. Gralnick¹⁵ reports 2 cases, in 1 of which a thirty-two-year-old woman was given insulin-coma treatment during the second and third months of pregnancy, she apparently recovered from the illness before term but delivered a macerated fetus. The other patient, who was thirty-one years old, was given both insulin and electric shock, between the first and fifth months of pregnancy, with no improvement, and also gave birth to a macerated fetus.

On the other hand, Bennett¹⁶ reports the successful treatment, with electric shock, of a number of women in all stages of pregnancy up to within two weeks of delivery, without incident to the pregnancy. He cites an article by Polatin and Hoch, who gave

CASE 33091

PRESENTATION OF CASE

A fifty-three-year-old retired general entered the hospital because of intermittent pain in the abdomen and back.

The patient was known to have had hypertension for seven years and had recently been following a "rice and fruit" diet. Six months before entry he began having episodes of "indigestion," with epigastric pain and gaseous discomfort sometimes accompanied by vomiting of recently eaten food. Usually, these episodes, which numbered five in all, followed meals that had exceeded the dietary restrictions. He then remained well until five and a half weeks before entry, when he suddenly began to have sharp pain in the lower chest radiating from "the pit of the stomach" down to the toes and "stiffening" him out. For about forty-five minutes the legs were paralyzed. He was unable to move his toes, turn his feet or bend his knees, but he could roll his hips. The pain persisted until a hypodermic injection relieved him two hours later. By that time the "paralysis" had completely disappeared. During that episode the patient was nauseated and vomited several times. For the next two weeks he continued to have pains in the lower abdomen, occasionally radiating to the epigastrium. He also ran a low-grade fever and developed a stubborn constipation, relieved only by enema. The patient's wife thought that he was slightly jaundiced for a while and that his bowel movements were lighter than usual but that they quickly returned to normal. The pain gradually receded, and the patient felt better again. Two weeks before entry he developed a "twisting" pain between the shoulder blades when he assumed certain positions. Five days later x-ray examination of the chest revealed a left pleural effusion and "congestion of the lungs." At that time 350 cc of bloody pleural fluid was removed. Seven days before entry a Graham test showed nonfilling of the gall bladder, there were no stones. Another thoracentesis yielded 400 cc of similar fluid. In the interval between the two thoracenteses the patient had developed pain in the left side of the chest and also had a slight non-productive cough.

The patient denied having had any chronic cough, dyspnea, orthopnea or hemoptysis.

Physical examination revealed a well developed man in no distress. Over the entire lower left side of the chest there were diminished breath sounds, diminished tactile and vocal fremitus and dullness. Over the left thoracic paravertebral area there was a loud, rushing bruit synchronous with the peripheral pulse. The heart was normal. There was some pain at the site of an old appendectomy scar in the right lower quadrant. Otherwise, the abdomen was negative. The left knee jerk was not obtained, the right was normal. One observer thought that the pulse in the left dorsalis pedis artery was less than that in the right. The femoral and posterior tibial pulses were equal.

The temperature was 98.8°F, the pulse 85, and the respirations 20. The blood pressure was 170 systolic, 100 diastolic.

Examination of the blood disclosed a hemoglobin of 12.2 gm and a white-cell count of 10,700, with 76 per cent neutrophils and 6 per cent eosinophils. The serum protein was 6.2 gm per 100 cc. The van den Bergh test was normal. The prothrombin time was 19 seconds (normal, 14 seconds). A blood Hinton test was negative. The urine was normal. An electrocardiogram revealed a normal rhythm at a rate of 80 and a PR interval of 0.18 second. The T waves were inverted in Lead I and low in Lead 2, with a sagging ST segment, and upright in Lead 3. The chest leads showed an upright T wave in Lead CF₁, a flat T wave in Lead CF₂, and an inverted T wave in Lead CF₃. There was a slight left-axis deviation.

X-ray examination of the chest revealed a rounded mass about 8 cm in diameter lying in the left superior mediastinum somewhat posteriorly (Fig. 1). The mass could not be distinguished from the aorta. There was no definite displacement of the mediastinum or esophagus, but the mass compressed the trachea. A considerable amount of fluid was present in the left pleural cavity, particularly along the mediastinum and posteriorly. The right lung field was clear. The heart was at the upper limits of normal, but its exact size could not be definitely determined. Both leaves of the diaphragm moved equally.

During the second night in the hospital the patient had another attack of epigastric pain, severe enough to require Demerol sedation. This episode was not accompanied by vomiting. On the next morning the abdomen was soft, and no masses were felt. There was some residual tenderness in the epigastrium. The bowel movements had become normal without the use of laxatives. On the eighth hospital day a thoracentesis was performed in the eighth interspace in the posterior axillary line, and 1000 cc of clear, yellow fluid was withdrawn. X-ray examination of the chest repeated after this procedure showed a shadow through the previously noted mass.

"Psychotherapy in General Practice" at the University of Minnesota. The course was arranged by the Commonwealth Fund and the Division of Postgraduate Education of the university. The plans, procedure and immediate results of this undertaking have been recorded by Smith.²⁰

A reading of Smith's pamphlet gives the impression that the student doctors and the teachers considered the course a striking success. One of the former, a recent graduate of an excellent school, is quoted as calling the program "the most remarkable educational experience I have ever had." The course comprised lectures, section meetings, seminars, films, clinics and individual interviews with patients.

Since about 50 per cent of the patients who consult the general practitioner have complaints for which there is no discoverable physical or organic cause, it is deplorable that medical education is so derelict that otherwise competent physicians do not know what to do for such patients except to make them worse or to help them speciously and temporarily by such a statement as "There is nothing wrong with you" or by resorting to a "pill," the trust in which has, in large part, been engendered by the medical profession. It would be beneficial if such a course as that offered at the University of Minnesota could be given throughout the country, within availability for all physicians who need it.

One of the instructors in the Minnesota course stated that the overall purpose of the course was to sensitize doctors to emotional problems in their medical practice. The principal defects in the teaching of psychiatry and clinical medicine are that the immediate and pervasive effects of emotion are not delineated and stressed — for example, that diarrhea or palpitation may mean anxiety and not enteritis or heart disease — and that the student does not learn the profound importance of giving the patient enough time to talk to the point, at least, of assurance that the physician is interested in him as a human being or, in other words, that the doctor listens with genuine, not feigned, interest.

Psychiatry is not limited to the care and treatment of the psychoses. Of equal importance are the study and treatment of personality problems and the consequent emotional reactions. Therapy is most successful when it is in the hands of a physician who is sincerely interested in his patients and who gives the patients enough time and intelligent attention to work out the problems if they are possible of solution.

DR BLAND If Dr Bauer does not ask me about the bloody fluid in the chest, I should like to ask him what sort of mass in the chest other than dissecting aneurysm involves the aorta and gives a sudden pain in the pit of the stomach, radiating down to both toes, with partial paralysis

DR BAUER On the way to this conference I asked Dr Bland if a syphilitic aneurysm ever dissected, and he said, "Yes, Dr Soma Weiss* reported three such cases" If such an event had taken place it could account for the initial attack of pain I must admit that when I read the record over last night I thought that this man had a dissecting aneurysm and my reason for retracting this diagnosis is largely on the basis of size On the other hand, I did not realize that a dissecting aneurysm could leak as it supposedly did during the first attack and not be fatal This may be the first example, of course

DR BLAND I am afraid that Dr Bauer misunderstood me The cases Dr Weiss demonstrated and reported had two processes in the same aorta syphilis and media necrosis The latter—not the syphilitic aortitis—was the cause of the dissection That might be the explanation of the onset of pain, radiating down the legs, and the partial paralysis

DR BAUER I wonder whether it was actual paralysis or inability to move the legs because of pain

DR CASTLEMAN Will you tell us what you know about this patient, Dr Leech?

DR CLIFTON B LEECH (Providence, Rhode Island) I was responsible for this patient before he entered the hospital I should be much happier about appearing here if my self-esteem were at a higher ebb than it is right now on account of the dimness of my perception in this case But I am not here to make excuses for my failure, but to give a few reasons that contributed to that failure

I had been responsible for this man since 1940, when fluoroscopy disclosed none of the abnormalities seen in the present x-ray films The impression that I got from the patient during his recent acute attack was rather different from what appears in the abstract I did not see him at 2 o'clock in the morning, when he had the sudden attack, because a nearby physician was called in to give a hypodermic injection, but I did see him at 10 o'clock that morning He did not appear seriously ill The pain was not in the chest entirely, it was largely abdominal, with some chest pain, as in the few attacks that he had had in the previous few months and that had cleared up within a few hours This pain persisted Regarding the paralysis in the leg, he mentioned that for a little while he could not move the left leg He said, "My left leg was paralyzed" I did not find anything the matter with the leg, and paid no particular attention to it The patient went on for several days with no com-

plaint aside from the pain, which was chiefly epigastric and more or less generalized He could not move his bowels although he had the urge The first of several enemas produced a little feces but after that none At the end of five days I called a surgical consultant I believed that the patient had a partial intestinal obstruction or partial ileus The surgeon had no doubt about the diagnosis of acute

FIGURE 2

cholecystitis, which I accepted The patient continued for a week with the same symptoms At no time did he complain of discomfort in the chest The blood pressure during the periods of pain had risen to unprecedented heights for him—216 systolic, 160 diastolic I took it two or three times when he did not have pain, and perhaps as a result of morphine, it was down to 180 systolic, 100 diastolic I thought that this was a peculiar course for acute cholecystitis and asked the surgeon to see the patient again He saw no reason to change the diagnosis and postponed surgical treatment until the patient was well enough to have x-ray studies of the gall bladder At that time I am sure that the patient had no fluid in the chest

During the x-ray study of the gall bladder, the roentgenologist stated that there was fluid through-

*Weiss S Clinical course of spontaneous dissecting aneurysm of aorta. *M Clin North America* 18 1117 1141 1935

This mass was interpreted as being the descending aorta or fluid in the medial portion of the pleural cavity. There was no definite erosion or destruction of bone. Following the pleural tap, the patient had a mild chest pain for several days. On the sixteenth hospital day, he began to complain of a sense of substernal pressure and small "stabbing pains" in the chest. Another chest film on the nineteenth hospital day showed little change except possibly a slight decrease in the amount of pleural fluid.

On the twentieth hospital day just after lunch the patient coughed up a small amount of bright-red

must one assume the presence of coronary heart disease?

DR. EDWARD F. BLAND: The changes were consistent with hypertension.

DR. BAUER: May I have some help on the x-ray films, Dr. Schatzki?

DR. RICHARD SCHATZKI: I think that everything is described in the record. Something was said about a shadow that showed through the mass.

DR. BAUER: Yes, following the aspiration of 1000 cc of fluid.

DR. SCHATZKI: The word "mass" was used in the sense of something that occupies space.

DR. BAUER: I did not understand the statement.

DR. SCHATZKI: This is the mass mentioned in the record. I do not see another shadow in that region.

DR. BAUER: Is it compatible with an aneurysm of the aorta?

DR. SCHATZKI: Yes.

DR. BAUER: Were there any pulsations during fluoroscopy?

DR. SCHATZKI: I do not believe so.

DR. BAUER: I must admit that when I first read the history my immediate reaction was that this patient had an aortic dissecting aneurysm. As I read on, however, I wondered whether all the findings could be explained satisfactorily on this basis. I did not believe that any type of mediastinal tumor, benign or malignant, could account for the sequence of events as recorded. I wondered somewhat about the possibility of a mediastinal abscess, but again there seemed little to justify or lend support to such an interpretation. Prior to seeing the x-ray films, I considered syphilitic aneurysm or a dissecting aneurysm of the aorta as the likeliest diagnostic possibility. From the record alone I was inclined to favor an aneurysm that had first dissected downward and subsequently upward. I must admit, however, that I found it difficult to account for the pleural effusion. I was not aware of the fact that a dissecting aneurysm could leak without being fatal. Having seen the x-ray films, I favor the diagnosis of an aortic aneurysm. I assume that it leaked for a time five and a half weeks prior to entry and finally ruptured, causing death. I am not certain that this diagnosis explains all the findings — for example, the two aspirations of bloody pleural fluid and a third that was yellow. There are a few other discrepancies. In favor of syphilitic aneurysm, however, were the x-ray findings, the bruit and the absent knee jerk on the left. True enough, the blood Hinton reaction was negative. The evidence in favor of syphilis is as complete as one might like.

DR. BENJAMIN CASTLEMAN: Do you believe that this was a saccular aneurysm rather than a dissecting one?

DR. BAUER: Yes, I do not believe that a dissecting aneurysm ever reaches this size, but I may be expressing my ignorance of dissecting aneurysm.

FIGURE 1

blood (enough to stain six Kleenex tissues). He had no pain. The physical findings at that time were unchanged except for a moderately loud apical systolic murmur that had not been heard previously. Fifteen minutes later the patient complained of a sudden, severe, crushing pain in the left side of the chest. He rapidly became white, clammy and restless. The blood pressure fell to 60 systolic, 40 diastolic. The breath sounds were diminished over the entire left side of the chest, and there was dullness in the posterior axilla. He was placed on shock blocks and given oxygen by Boothby mask, as well as 1000 cc of whole blood. The blood pressure returned to 130 systolic, 80 diastolic, and his condition remained satisfactory for twelve hours. On the following morning he again coughed up a small amount of bright-red blood and complained of severe pain in the center of the chest and of inability to breathe. He became restless, pale and sweating and died within thirty minutes.

DIFFERENTIAL DIAGNOSIS

DR. WALTER BAUER: Could the electrocardiographic changes have been due to hypertension? Or

mouth floor and elevating the tongue. There was an area of anesthesia, about 3.5 cm in diameter, at the angle of the mouth on the right.

The routine admission laboratory findings were normal. The blood calcium was 9.2 mg, and the phosphorus 4.2 mg per 100 cc, and the phosphatase 40 Bodansky units.

An x-ray film taken in the Tumor Clinic just before admission revealed a large soft-tissue mass arising from the chin and protruding slightly to the left side (Fig. 2). The anterior aspect of the jaw on both sides, as well as in the region of the chin, showed extensive bone destruction involving the lower two thirds of the jaw. The destructive process had caused the isolation of several bone fragments. No calcification was seen in the soft-tissue mass, and no evidence of periosteal activity was present. An x-ray film of the mandible and of the upper cervical spine taken two days after admission revealed bone destruction as far as the second molar area, with involvement of several teeth.

On the fourth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR HENRY M. GOLDMAN: As can be seen from a photograph of this girl, the tumor had grown to a considerable size before admission.

The history states that the patient had a painless mass poorly attached to the jawbone on the right side. The fact that the mass was poorly attached

FIGURE 1

to the jawbone suggested to her physician that it was an inflammatory "gland," and he gave her some pills. The mass did not regress, however, and on an attempt to drain it, only blood was recovered. One can assume that a tumor already existed and that the "gland" was a part of the lesion. The fact that the patient had pain around the teeth a month later seems to denote that the tumor had invaded the body of the mandible and had involved the periapical region of one or more teeth. This tooth or those teeth were probably loose, a finding that is often the first evidence of a malignant lesion of the jaw. The x-ray film taken at that time was described as "not remarkable." I highly question this because

there must have been some change, since a film taken ten days later showed extensive destruction of the mandible. This brings up two possibilities: in the first place, the tumor may have invaded along the mandibular canal, causing extensive destruction in a short time, and secondly, extensive invasion may have taken place because of a highly malignant tumor. The patient developed numbness of

FIGURE 2

the right chin and the lower lip, which reinforces the suspicion that the tumor had invaded the mandibular canal and had involved the inferior mandibular nerve.

Reviewing the history up to this point, I believe that the tumor was originally periosteal or endosteal and later extended peripherally and internally.

The blood studies were negative and rule out any of the skeletal diseases.

X-ray examination showed an osteolytic process involving the middle portion of the mandible and appearing as spotty irregular radiolucent areas. A large, soft-tissue mass was seen extending from the jaw, no calcification was observed in the soft tissues and no periosteal activity was present.

In summarizing the history, one can say that this was not an inflammatory lesion. This rules out an osteomyelitis or anything of that nature. We know that this was a rapidly growing, invasive tumor and therefore a highly malignant one.

The first thing to think of is an osteolytic osteogenic sarcoma, with which the patient's age and the roentgenologic evidence are consistent, and on the law of chance that is a reasonable diagnosis to make.

out the chest. The signs of fluid were unmistakable. I had questioned the patient closely about chest symptoms, and he said that he had a little pain between the shoulder blades if he moved in a certain way. Paracentesis yielded 350 cc of uniformly bloody, almost ruby-red fluid. My thought was that in addition to the hypertension and acute cholecystitis he had a mediastinal tumor with pleural involvement, and I had no hesitancy in allowing him to go back to the roentgenologist's office for completion of the studies, which were reported to me as showing a large left superior mediastinal mass, with pleural fluid, and a nonfunctioning gall bladder.

Two days after the first chest tap I again removed 400 cc of uniformly bloody fluid. For the first time the patient admitted discomfort in the area of the tap. I accepted the roentgenologist's diagnosis and made arrangements for him to come up to see Dr. Churchill. Although the record does not so state, he had a third attack two days before he came here. He also had a small amount of bloody fluid at that time.

A PHYSICIAN: Was he jaundiced at that time?

DR. LEECH: No.

DR. BAUER: I should like to go back to my first diagnosis — a dissecting aneurysm of the aorta.

CLINICAL DIAGNOSIS

Dissecting aortic aneurysm, with rupture.

DR. BAUER'S DIAGNOSIS

Dissecting aneurysm of aorta, with rupture.

ANATOMICAL DIAGNOSIS

Dissecting aneurysm of aorta, with rupture into left pleural cavity and with localized expansion and partial healing.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: At autopsy the left pleural cavity contained almost 3000 cc of blood. The source of this blood was a ruptured aortic dissecting aneurysm (Fig. 2). The intimal tear was located just beyond the arch, at the beginning of the descending thoracic portion. It was a triangular tear leading into a large sac, 8 cm in diameter, that was lined with partially organized clot and filled with fresh blood. This sac was really a greatly expanded portion of the dissecting aneurysm, or what might be termed a medial hematoma, because it is within the media that dissection always occurs. It produced the large mediastinal shadow observed on x-ray examination. Farther down the aorta we found another similar but smaller medial expansion that was almost completely filled with organized clot and a little fresh blood. These two sacs were connected. Following the aorta down still farther we found dissection as far as the iliac arteries. This portion of the dissection, however, was organized, measuring at the most 1 mm in width. A similar healed dissection extended

proximally from the intimal tear down to the aortic valve. It did not appear to involve the coronary mouths. There was evidence of some dissection around the mouth of the right renal artery and especially around several of the lower intercostal arteries, where there were localized expansions within the aortic wall measuring up to 1 cm in diameter. These were undoubtedly the cause of the transient leg paralysis, since the intercostal arteries supply branches to the spinal cord.

I believe that the sequence of events was as follows. The intimal tear and dissection occurred five and a half weeks before entry. Most of the blood in the aneurysm organized, leading to obliteration of the channel, except in the region of the intimal tear, where the localized medial hematoma increased gradually in size until the pressure was so great that the external wall gave way. There probably was a slow oozing of blood through this sac, which would account for the hemorrhagic pleural fluid removed by Dr. Leech two or three times. If clear fluid was obtained, I believe that the blood had settled and that this was supernatant fluid above the blood clot.

A PHYSICIAN: Why did the patient have a hemoptysis?

DR. CASTLEMAN: The aneurysm was adherent to the left upper lobe, and there was a little oozing of blood into the lung parenchyma.

There was no evidence of syphilis. This was a case of media necrosis aortica cystica. We have had one other case of aortic dissection with a large medial hematoma such as this.

CASE 33092

PRESENTATION OF CASE

A seventeen-year-old unmarried salesgirl was admitted to the hospital because of a painless mass in the jaw.

About three months before entry the patient noted a hard 2-cm mass, which seemed poorly attached to the jawbone on the right. A physician thought that it was a "gland" and gave her pills. When it did not regress he attempted incision and drainage but obtained only blood. About a month later, when the left lower incisor teeth began to ache, the patient was referred to a dentist for x-ray studies. Three weeks later the swelling had enlarged, the right jaw had begun to ache, but an x-ray film was not remarkable. A repeat x-ray examination ten days later revealed extreme destruction originating within the right side of the mandible and extending to include the symphysis. A week before entry numbness developed in the right chin and lower lip.

Physical examination revealed a symmetrically enlarged, hard, insensitive mass about the size of a pear jutting from the chin (Fig. 1). It was continuous with the mandible and lay immediately beneath the dusky tense skin, presenting inside the

nant, and the prognosis is poor. Some that I have seen have invaded the bone, and others have not. In one case, spicules of bone extended into the tumor, as seen in osteogenic sarcoma. These spicules are generally metaplastic bone growing from the jaw into the tumor. The third is the central type of sarcoma, which develops most frequently in the mandibular canal, from connective tissue around the nerves or blood vessels, with consequent pain, paresthesia, numbness of the lip, and loose teeth. Finally, the tumor generally is visible inside as well as outside the mouth, changing the appearance of the face. I believe that this tumor originated from the periosteum and invaded the jaw secondarily.

DR GRANTLEY W TAYLOR: We went through much the same process of reasoning as Dr Goldman. In the Tumor Clinic, our first effort was to get an accurate diagnosis of the histologic type, because if the tumor was sensitive to radiation, we thought that that might be the proper way to handle it. Operation seemed almost impossible because of the extension of the tumor far back in the floor of the mouth, but following biopsy, which intimated to us that the tumor would be unlikely to respond favorably to radiation therapy, we decided on radical operation. We were able to remove the entire tumor, apparently without leaving any local process behind. We took some encouragement from the fact that before operation there was no evidence of dispersion or dissemination of the tumor. As Dr Thoma pointed out, fibrosarcomas in relation to the mandible behave differently in general from those elsewhere in the body, may be confined as a local process longer and are less likely to disseminate. We therefore have some hope that this girl may have been cured by the mutilating operation. If so, she has her whole life before her, and the problem of restoration of function can be carried out at leisure.

CLINICAL DIAGNOSIS

Sarcoma of jaw

DR GOLDMAN'S DIAGNOSIS

Periosteal fibrosarcoma of jaw

ANATOMICAL DIAGNOSIS

Periosteal fibrosarcoma of jaw

PATHOLOGICAL DISCUSSION

DR MALLORY: On the biopsy we reported osteogenic sarcoma. With further study I have changed my mind.

The photograph of the resected specimen (Fig 3) shows that nearly all the mandible was resected. The bulk of the tumor was extraosseous, but there was tumor growth within the mandible itself. The sections disclosed a spindle-cell tumor that was rapidly growing, evidently highly malignant and rather poorly differentiated. In one of eight sections two small spicules of osteoid were found. Some question arises whether on that basis it was fair to consider this an osteogenic sarcoma. My opinion is that that diagnosis was not correct, that these spicules represented a slight reactive periosteal bone formation, which Dr Thoma mentioned, and that the tumor must be classified as a periosteal fibrosarcoma.

DR VINCENT DOLE: Do you think that the incision done elsewhere had any influence on the spread or extension of the tumor?

DR MALLORY: I cannot answer that question. Such an incision is certainly something that all of us prefer not to have done.

A periosteal fibrosarcoma is suggested by the fact that the mass started in either the periosteum or the endosteum. The patient was in the correct age group for this tumor also. The lack of osteoblastic activity in the x-ray film makes me lean toward a fibrosarcoma. I think that a Ewing tumor should also be considered — the age is again right. The

FIGURE 3

history does not mention any injury or blow, but that is a possibility. There was no history or x-ray evidence of multiple myeloma, since this was a solitary lesion and did not run the course of myeloma, I shall dismiss that diagnosis. I also thought of a neurogenic fibrosarcoma, for which I think the possibilities are good, an angiosarcoma and finally a metastatic tumor. This could have been a metastatic tumor from a primary tumor in some other area — a kidney tumor, for instance. That is not too rare. I think that that possibility should definitely be considered.

Going through such a differential diagnosis, one comes down to a preoperative diagnosis of either osteogenic sarcoma or periosteal fibrosarcoma. I finally concluded that it was a highly malignant tumor that had probably metastasized and should have been resected immediately and that it was a periosteal fibrosarcoma.

DR JAMES R. LINGLEY: The tumor is adequately visualized in this lateral view, which shows a mass within the jaw. There is no calcification. The lesion is predominantly destructive. The only new bone

is anteriorly, with a little periosteal malformation. The process involves more of the right side than the left.

DR JOSEPH C. AUB: Do you have the x-ray film taken ten days previously?

DR TRACY B. MALLORY: They were taken in another hospital, and we were not able to get them.

DR AUB: It is hardly likely that they were normal.

DR MALLORY: We all agree on that. Do you wish to express an opinion, Dr. Sosman?

DR MERRILL C. SOSMAN: The lesion looks purely destructive. There is no obvious new-bone formation, and no reactive bone, such as one might expect with an inflammatory process. The only new bone is periosteal, anteriorly and just below the incisors. This fits in quite well with Ewing tumor. The margin of an osteogenic tumor is often raised, forming the reactive triangle described by Codman. The tumor spreads along the shaft, raising the periosteum and forming a marginal triangle until the tumor destroys the new bone. One thing not emphasized is the point of origin, which is apparently the anterior margin of the bone and not the tooth. All the roots of the teeth, so far as I can see, are normal, so that the tumor presumably did not originate from any of the dental structures per se. We can rule out the adamantinomas and the whole group associated with the embryology of the dental structures in the development of this tumor. I should interpret it as a highly malignant growth, probably osteogenic sarcoma or Ewing tumor.

DR KURT H. THOMA: It is significant that the tumor was not entirely in the bone, which is the site of an adamantinoma, although it is not entirely outside. In tumor of the jaw the main point to decide is whether it originated in the bone and grew in both directions — in the manner of a Ewing tumor or an osteogenic sarcoma — or whether it remained within the limits of the bone as do the central tumors of nonosteogenic origin, or whether it developed from the periosteum and later invaded the bone. If we can trust the former x-ray diagnosis and also the statement regarding the onset of the disease, it seems to me likely that the tumor originated from the periosteum. Therefore, it was a periosteal fibrosarcoma, which invaded the jaw.

There are three types of fibrosarcoma that occur in the jaw. One, which is intraoral, developing from the periosteum of the alveolar process or periodontal membrane, forms multiple masses and is not so malignant as the subcutaneous type. There is a series of 35 cases reported by Pollack* in 1936 in which 25 patients had lived from six months to twelve years without recurrence, 3 were unimproved after operation, 3 had recurrences in from two to eight years, and in 3 the outcome was unknown. The second type of fibrosarcoma, which develops in the subcutaneous region of the jaw, is more malig-

*Pollack, W. *Das Schicksal der malignen Tumoren aus der Westdeutschen Kieferklinik seit dem Jahre, 1920*, Düsseldorf 1936.

the school nurses and, indeed, to the teacher who is closest of all to her charges

Finally the practicing physician concerned — the family doctor or pediatrician — must be brought into the picture. Only with his interest and co-operation can a successful, fully rounded school health program be developed. On his advice a final decision often rests, and it is frequently he who must see that corrective measures are carried out.

SMALLPOX DECLINES

"SMALLPOX, once the scourge of our forefathers," wrote the late Dr. Benjamin White,* when he was director of the Massachusetts Antitoxin and Vaccine Laboratory, "has become such a rare disease in Massachusetts that we have become unmindful of its pestilential power. We do not realize that it still exists with all its horrible features, and that instead of being conquered, it is at best only held at bay by the continued practice of vaccination."

The world has always had its various pestilential visitations, coming at greater or less intervals over the centuries, and eventually sparing those countries where scientific control has been most intelligently applied. Smallpox of these, has been the most tenacious, the most persistent, the one most frequently recurring in the long history of the scourges of mankind. It is known to have existed in Asia before the Christian Era, it came to Europe as early as the sixth century, reaching its height in the seventeenth and eighteenth centuries, it invaded the New World in the wake of the earliest pioneers. Thus, in the German-speaking countries, according to White, over 65,000 persons died of smallpox in 1796, in the early nineteenth century, 40,000 people succumbed annually in Prussia, and Boston itself was visited by smallpox in epidemic form twelve times between 1649 and 1792. Admiral Berkeley, in a speech before the House of Commons in 1802, said "It is proved that in this United Kingdom alone, 45,000 persons die annually of the smallpox, but throughout the world what is it? Not a second is struck by the hand of Time but a victim is sacrificed upon the altar of that most horrible of all disorders, the smallpox."

*White B. *Smallpox and Vaccination*. Harvard Health Talks. 90 pp. Cambridge: Harvard University Press. 1924.

These words are written about a disease known since 1798 to be preventable and one against which the technic of prevention has been of late years so successful that in 1945 only 346 cases were reported in the entire United States, and only 5 in Canada. These figures, according to the Metropolitan Life Insurance Company's Information Service, represent the lowest ebb that smallpox has ever reached in the United States and, incidentally, furnish an example of what preventive medicine can accomplish, particularly when these cases are compared with 48,920 reported as recently as 1930. It is of local interest to note that the five New England states are included among the thirteen that were entirely free of the disease, and that the thirteen, although not representing exactly the original thirteen colonies, are all on the Atlantic seaboard.

It must be constantly emphasized, however, that eternal vigilance is the price paid for security that where vaccination lapses smallpox occurs. Any reservoir of infection is the potential focus of future smallpox epidemics, and the return of members of the armed forces from overseas constitutes an extra hazard. To servicemen returning from the Orient can be attributed the recent outbreaks of virulent smallpox in San Francisco and Seattle, which fortunately, were quickly brought under control by quarantine and mass vaccination.

MASSACHUSETTS MEDICAL SOCIETY COMMITTEE TO MEET WITH GENERAL HAWLEY

Members of the Massachusetts Medical Society who wish to participate in the plan for the local care of veterans and who have not yet sent in their registration forms are urged to do so at once.

Those physicians who have already registered as specialists, and who would also like to give general physical examinations should communicate with Humphrey L. McCarthy, M.D., 479 Beacon Street, Boston.

HUMPHREY L. MCCARTHY, *Chairman*

DEATH

GRANT — Justin F. Grant, M.D., of Boston, died January 26. He was in his sixty-ninth year.

Dr. Grant received his degree from Johns Hopkins University School of Medicine in 1903. From 1903 to 1910 he was professor of anatomy and pathology at the University of West Virginia and from 1910 to 1912, professor of anatomy at the Atlanta College of Physicians and Surgeons. He had practiced in Boston for many years. He was a fellow of the American Medical Association.

A sister, a son and a daughter survive.

SCHOOL HEALTH SERVICES

EVERY so often, at more or less irregular intervals, we become conscious of the fact that the child is father of the man and that something ought to be done about it. There may be many causes for such awakenings, but they are sure to come after the examination of recruits in time of war — a chastening experience. They may result in another White House conference or in a nationwide study of child health services or in a determined reformulation of our school medical services.

School medical services have come much to the fore in the last few years. They have been studied by a committee of the American Academy of Pediatrics, with recommendations. *Suggested School Health Policies* has been published by the Health Education Council, and the Massachusetts Medical

Society, through a subcommittee, has investigated local conditions in the Commonwealth. The whole situation is admirably summarized elsewhere in this issue of the *Journal* by Dr. George M. Wheatley, assistant vice-president of the Metropolitan Life Insurance Company.

Four essential factors are necessary for the improvement of medical service in the schools "co-operation between education and public-health authorities, provision for health services in the school that are satisfactory learning experiences for children, properly qualified school health personnel and the development and strengthening of relations with the medical profession."

At present in many states there are heartaches over the division of responsibility for school health between departments of education and departments of health. Friction and jealousy exist where properly worked out co-operation could bring contentment to both parties and improved service to the public.

The value of the physical examination often suffers, both because of undue restrictions that have been imposed by overmodest lawmakers who have refused to allow sufficient clothes to be removed from the child and because of overspecific requirements, such as where an annual examination is established by law regardless of lack of personnel to carry it out properly.

The function of the examination as a learning experience to the pupil is lost if it is casual or hurried, with no opportunity for a real "consultation", and with younger children, corrective measures usually fail if the parent is not induced to be present. The time of the examination, if it is a good examination, has been aptly termed the "most 'teachable moment' — the best educational opportunity that exists in the schools," and the moment is often lost.

The school physician must himself be rescued from a situation where, often, as a harassed, underpaid official, untrained for the particular work in which he is engaged, he is doing poorly a part-time job for what little money there is in it. School health is a dignified, vital branch of public health, and it should be in the hands of capable, well trained, adequately paid career men and women. This applies not only to the physicians and dentists but to

CORRESPONDENCE

ILLEGIBLE AND INCOMPLETE DEATH CERTIFICATES

To the Editor Since assuming the office of City Registrar I have become increasingly aware of a condition in the writing of original certificates of death by physicians that creates a serious hardship on all who are engaged in the processing of these documents, including the personnel of the Registry Department. The certificates, in many instances, are illegibly written, the required data are lacking and there are numerous other conditions which make the copying of these records almost an impossibility without soliciting confirmation by telephone from the physician who made out the certificate or referring to medical dictionaries in an effort to determine clearly the causes of death.

It is not my purpose to become critical of the medical profession, recognizing only too well the tremendous task imposed on physicians at this time, but it is my feeling that if this matter could be brought to their attention an improvement in the quality of the records being forwarded to this department might be brought about.

AORTIC OCCLUSION

To the Editor. Dr. Edward D. Maire's article, "Coarctation of the Aorta," which appeared in the January 2 issue of the *Journal* was stimulating. He failed, however, to mention a condition in his paper that I believe should be called to the attention of your readers. This is atheromatous occlusion of the abdominal aorta or of both common iliac arteries.

The brachial blood pressure in many cases is elevated. The pressure in the lower limbs is invariably low. The femoral pulsations are reduced or absent. Symptoms due to the ischemia of the lower extremities, such as intermittent claudication, pain and early fatigability, are usually present. In the differential diagnosis evidence in favor of coarctation of the aorta, such as scalloping of the ribs and absence of the aortic knob, is lacking. Evidence in favor of atheromatous occlusion consists of the following: the onset of initial symptoms past middle age, the presence of x-ray findings of calcification of the aorta or iliac or femoral arteries, and the presence of diabetes or hypercholesterolemia. The abdominal aorta may also be occluded from other causes, such as an ovarian cyst. In such cases the presenting symptoms usually include the intra-abdominal mass.

Owing to the fact that there is no practical method of exploration of the abdominal aorta, its occlusion is frequently overlooked. A method of retrograde abdominal aortography has been reported by Dr. P. L. Farnas (*Surgery* 18:244, 1945, and *American Journal of Roentgenology and Radium Therapy* 55:448, 1946). I doubt, however, that this method will receive widespread use in this country.

BOOK REVIEWS

Principles of Dynamic Psychiatry, Including an Integrative Approach to Abnormal and Clinical Psychology. By Jules H. Masserman, M.D. 8°, cloth, 322 pp., with 4 plates. Philadelphia and London: W. B. Saunders Company, 1946. \$4.00.

This is another volume of psychiatry that will not be generally adopted as a textbook for academic undergraduate teaching. The author states that his immediate purpose of getting into print is to express certain fundamentals of modern dynamic psychiatry that are now being taught by him and his colleagues only through lecture and precept. He has sought for books that, breaking with tradition, present the fundamentals of dynamic psychology and clinical psychiatry briefly, clearly and systematically. In his attempt to bring together the psychoanalytic, biologic and physiologic approaches, his formulations are not always presented briefly, clearly and systematically.

Behaviorism is rather in the foreground, illustrative clinical records are utilized freely, and original animal experiments

contribute the most intriguing part to the book. The student may be misled to believe these to be the stuff that so-called "dynamic psychiatry" is made of. "Biodynamics of Normal and Abnormal Behavior" is a long and involved chapter in which the author attempts to correlate various theories, some of which are fundamentally and traditionally opposed to each other. He admonishes man to cease thinking of himself as so different from other animals, and he states that "psychology and psychiatry may profit immeasurably by becoming more 'catomorphic' or even 'amoebamorphic' as corrective steps toward the ultimate conceptual integration of all behavior theory."

The author has put much work in this volume, which will be read with interest by specialists. He refers repeatedly to a companion volume on clinical psychiatry and therapy that is to follow.

Considerable space is given to neurotic reaction types and borderline cases. The psychoses are not the center of the work, and the author has studiously deviated from the orthodox diagnostic formulations and psychiatric clinical entities.

There is a complete bibliography and a glossary of about twelve hundred psychiatric terms that will be helpful to the student.

Modern Trends in Child Psychiatry. Edited by Nolan D. C. Lewis, M.D., and Bernard L. Pacella, M.D., with the assistance of Gertrud M. Kurth, Ph.D. 8°, cloth, 341 pp. New York: International Universities Press, 1945. \$6.00.

This volume contains the lectures on child psychiatry and guidance given at the New York State Psychiatric Institute by leading authorities in 1943 and 1944. The various aspects and manifestations of anxiety and the primary behavior disorders, psychiatric reactions and delinquencies in children are dealt with. New methods and techniques in diagnosis and therapy, as well as the psychobiologic approach, emphasizing parent-child and living social relations, are discussed. This book is valuable as a record of the lectures and should be in all psychiatric reference collections.

Bioenergetics and Growth, with Special Reference to the Efficiency Complex in Domestic Animals. By Samuel Brody, Ph.D. A publication of the Herman Frasch Foundation. 8°, cloth, 1023 pp., with illustrations and tables. New York: Reinhold Publishing Corporation, 1945. \$8.50.

This volume records investigations made in the comparative study of the energetic efficiencies of agricultural processes. The subjects discussed cover a wide territory. Many of the factors influencing efficiency, such as enzymes, minerals, vitamins and hormones, are analyzed largely with the aid of the literature on the various subjects. The material is well documented and contains much of value in comparative physiology, especially concerning homeostasis, calorimetry, metabolism, growth rates, aging, nutrition and muscular work. The text is well written and illustrated with graphs, charts and tables. It is printed with a good type on good paper. This valuable work should be in all physiologic reference collections.

Journal of the History of Medicine and Allied Sciences. Vol. 1, No. 1 (January, 1946). 4°, cloth, 182 pp. New York: Henry Schuman, 1946. \$2.50.

The publication of a new quarterly journal devoted to medical history and the allied sciences will receive a warm welcome from medical historians in America and throughout the world. With the coming to an end of the *Annals of Medical History*, the United States was left with only one journal, the excellent *Bulletin of the History of Medicine*, to supply a growing need for publications in this field. Many foreign journals, of similar scope, were discontinued during the war, some permanently.

The new journal fills a want and does it admirably. Neat in appearance, expertly edited and well printed and illustrated, this publication fully justified its existence in the first number, issued in January, 1946. Subsequently, three other numbers have more than come up to expectations set by the initial issue. The editor, Dr. George Rosen, is ably assisted by a board of qualified historians and consulting editors from many countries. No student of medical history can afford to miss a single number, and all libraries, medical as well as general, should subscribe.

A HUNDRED YEARS AGO

Letters and printed reports by the last steamer show that the Boston Letheon is well received in London. Mr. Liston, the great surgeon, has amputated twice with marked satisfaction, while the patient was under its influence. — On Wednesday last, although the weather was unfavorable, a good number of Counsellors of the Massachusetts Medical Society were punctually present at 11 o'clock, the hour designated in the notices of their meeting. Some alterations were made in the by-laws, which in due time will be published. Dr. Bigelow, the President, announced that he should not be a candidate for office the ensuing year. A change of feelings, and of policy, too, on the part of some of the gentlemen who opposed the election of delegates to the last National Medical Convention, was as striking as it was gratifying. The following members were nominated from the Chair, and elected delegates to the next National Convention in May, viz, Dr. Stephen W. Williams, Deerfield, Dr. Enoch Hale, Boston, Dr. Elisha Huntington, Lowell, Dr. A. L. Peirson, Salem, Dr. Royal Fowler, Stockbridge, Dr. J. V. C. Smith, Boston, Dr. Joseph Sargent, Worcester, Dr. Z. B. Adams, Boston, Dr. Lyman Bartlett, New Bedford, Dr. E. W. Carpenter, Sandwich, Dr. Wm. Bridgeman, Springfield, Dr. O. W. Holmes, Boston, and Dr. George C. Shattuck, Jr., Boston. Other business was despatched actively, yet with due regard to the best interests of the institution and those associated with it. — A lady, in the West, recently gave birth to four daughters, all represented to be doing well. — In the fifth Massachusetts Registration Report, several tables are presented to show the average value of life in persons who pursue different occupations. Fourteen clergymen were carried to an aggregate of 897 years, which shows the average age to have been 64.07 years. Eight lawyers lived to an average of 59, by which it appears that there is nothing essentially injurious to the machinery of organic life in that profession. Twenty-one physicians had allotted to them an average of only 47.64 years. There are few or no holidays for this class of men. Professional cares prey upon constitutions operated on by other forces, such as exposure to all the vicissitudes of weather, broken sleep, irregular meals, etc., which individually war against a long life. Teachers are on the gain in point of longevity, which may probably have been caused by the better systems of ventilation demanded from one season to another by those who are especially interested in the public health. Those styled gentlemen, in the old Puritan Bay State, seem to have spun out the thread of life to a very satisfactory period. A furnace man had the shortest life in the whole column of 137 trades and professions. It may be remarked, with safety, that there is room for vast im-

provement in this new idea, in the United States, of registration. — Dr. I. P. Smith, of Gloucester, reports the case of a woman who was married young and at the time considered a remarkably slender girl, being subject to cough upon the slightest exposure. Her only brother and sister both died of *tubercular phthisis* and both parents also died of the same disease. She was 39 years old on October 28th, 1846, and never had a sick day since her marriage December 9th, 1826, except the usual sickness consequent on parturition. During this period she has given birth to eight children all of whom are now living and in perfect health. She has been constantly nursing for a period of nearly twenty years — never weaning one child till the birth of another compelled her to, for the convenience of the infant. More than once, when in labor, Dr. Smith has seen her child of the last birth at the breast. He wishes to know whether, if similar cases with a like favorable result are reported, *protracted lactation*, especially during pregnancy, might properly be inferred to possess a prophylactic power, even when there exists a well-marked hereditary predisposition to pulmonary disease. — A public announcement has been made in New York of another new "discovery" under the name "spirometer" for ascertaining the condition of the lungs and "air passages." Physicians and the public have been lately invited to the Astor House to inspect the instrument. Those who have responded to the call have been introduced to a gasometer, resembling those seen in every chemist's laboratory and used in ordinary by the public exhibitors of the laughing gas. Its only novelty or improvement consists in a tube movably attached to the top of the gas holder, while itself is filled with water, and a scale attached to the top of the cylinder designed to show the amount of air which an individual can expire by blowing into the tube. The idea that even having ascertained the capacity of the lungs, by measuring the volume of air expelled by a full expiration, we should thereby learn anything of the true pathological state, in the variety of morbid affections of the pulmonary tissues, is a *reductio ad absurdum* in itself, besides being at war with medical philosophy and the lessons of experience. — The *Boston Transcript* intimated last week that Dr. Warren was about resigning his connection with the Medical College in this city. — At a meeting of the Committee on Dissertations of the Boylston Medical Society held February 10th, three prizes were awarded. The dissertations this year, we learn, were of an unusually high order, and some difficulty was experienced in making a selection by the Committee. — Extract from the *Boston Medical and Surgical Journal*, February, 1847.

Contributors to the various sections are all well known in their fields. The various chapters are written in a clear, common-sense manner. There should be no difficulty in following the instructions given. Although one might prefer, for the sake of completeness, to have all motor skeletal difficulties discussed, only those amenable to surgical therapy are mentioned. Most doctors with experience in orthopedic surgery will not agree unreservedly with the treatment suggested, but they will learn — as the reviewer has learned — many helpful new points in therapy. The second volume is especially well done. The format is good, and the printing and the illustrations are excellent. These helpful and practical books can be recommended and will be most useful to orthopedic and industrial surgeons.

Correction. In the listing of *A Bibliography of Infantile Paralysis*, a review of which appeared in the January 2, 1947, issue of the *Journal*, it is erroneously stated, "Compiled by Ludwig Hektoen, M.D." The statement should read, "Compiled by Ludwig Hektoen, M.D., and Ella Salmonsens."

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

The Electron Microscope. An introduction to its fundamental principles and application. By E. F. Burton, head of the Department of Physics and director of the McLennan Laboratory, University of Toronto, and W. H. Kohl. Second edition. 8°, cloth, 325 pp., with 125 figures and 66 plates. New York: Reinhold Publishing Corporation, 1946. \$4.00.

This second edition of a standard work has been revised throughout, and the text has been rearranged. The aim of the book is to provide an introduction to the fundamental principles and applications of the electron microscope, and in this connection some material has been eliminated as being too special for the scope of the book. The detailed description of the Johansson-Brüche electrostatic electron microscope has been omitted from this edition, and the chapter on the history of the electron microscope has been eliminated, parts of this chapter being incorporated in other chapters. The chapters on electron optics have been enlarged, and the chapter on the compound magnetic electron microscope has been rewritten completely and much new material added. In the chapter on the application of the microscope, which has been largely rewritten, the illustrations of the accomplishments of the microscope are included. A complete bibliography recently prepared by Claire Marton, of Stanford University, and Samuel Sass, of the University of Michigan, is included with the permission of the authors and the publishers. Some data have been added concerning the organization of the Electron Microscope Society of America. Both the first and second editions of this book should be in all libraries having an interest in the subject.

Public Health the American Way. By H. B. Anderson. 8°, cloth, 238 pp. New York: Citizens Medical Reference Bureau, Incorporated, 1945. \$2.50.

The central thought that this book seeks to convey is that compulsory sickness insurance and similar schemes to socialize medicine nullify the Bill of Rights of the Constitution.

Trends of Mental Disease. American Psychopathological Association. 8°, paper, 114 pp. New York: King's Crown Press, 1945. \$2.00.

This small monograph, by various authors, constitutes a statistical analysis of the incidence of mental disease. The authors discuss the census statistics of patients in hospitals for mental disease in the period 1933-1942, the expectation of mental disease in New York State during the years 1920, 1930 and 1940, and the trend of mental diseases in Illinois during the period of 1922 to 1943. Two concluding chapters

consider the trends of mental disease in the Navy and the neuropsychiatric screening of Selective Service registrants in New Jersey. The first chapter forecasts the trends of mental disease in the United States during the period 1940 to 2000.

A Blind Hog's Acorns. Fignettes of the maladies of workers. By Carey P. McCord, M.D. 8°, cloth, 311 pp., with illustrations by Strobel. Chicago: Cloud, Incorporated, 1945.

The author, who is a specialist in the field of occupational diseases, relates his experiences as an industrial physician.

1021 Answers to Industrial Health and Safety Problems. Edited by Jack C. Weiss, editor, *Occupational Hazards Magazine* and the following associates: John MacKovace, B.A., Lester P. Aurbach, B.A., Helen A. Buchman, M.A., and Jerome R. Peskin, M.A. 8°, cloth, 699 pp., with 327 illustrations. Cleveland: Occupational Hazards, Incorporated, 1943. \$10.00.

This volume constitutes in a way an encyclopedia of industrial medicine. The text is divided into twelve divisions falling into two major classifications — industrial diseases and hazards, and safety provisions against accidents. Special reading bibliographies are appended to each subject. A valuable appendix on the classification of potential hazards by chief industries concludes the text. A large comprehensive index makes available all material contained in the volume. The work should prove of value as a ready reference source to all those interested in public health and industrial medicine.

The Principles and Practice of Tropical Medicine. By L. Everard Napier, F.R.C.P. (London), consultant to the Secretary of War, visiting lecturer on tropical medicine, Army Medical School, and visiting lecturer on tropical medicine, Harvard Medical School. 8°, cloth, 917 pp., with 195 illustrations and 32 tables. New York: The Macmillan Company, 1946. \$11.00.

This new textbook on tropical medicine is directed wholly for clinical and preventive application. The author has attempted to give an accurate and concise account of the more important tropical diseases from the viewpoint of epidemiology, etiology, pathology, symptomatology, diagnosis, prevention, treatment and prognosis, and discusses in a general way such relevant subjects as methods of mitigating the effects of a tropical climate, nutrition and anemia in the tropics and snakes and snake bites. The material is well organized, and many of the subjects are preceded by a short, historical paragraph. Selective lists of references are appended to each subject. Good indexes of subjects and authors are appended to the text. This new textbook by an outstanding authority should be in all medical libraries and the libraries of physicians interested in tropical medicine.

Public Baths and Health in England, 16th-18th Century. By Charles F. Mullett. Supplement No. 5 to the *Bulletin of the History of Medicine*. 4°, paper, 85 pp. Baltimore: Johns Hopkins Press, 1946. \$1.50.

This historical monograph is well documented, with references to the popular literature of the period. Appended to the text is a bibliography of books and pamphlets on the subject that should be of value to all interested persons. This monograph should prove valuable as a reference source on the subject.

An Introduction to Essential Hypertension. By Richard F. Herndon, M.D. 8°, cloth, 88 pp. Springfield, Illinois: Charles C. Thomas, 1946. \$2.50.

In this small book the author has presented a concise statement of what seems to be the present concept of hypertension in such a way that the ordinary practitioner of medicine can use it as a text for first reference. Following a definition of hypertension, the various aspects of the condition are considered in the following order: etiology and mechanism, physiology, pathology, clinical aspects, prognosis, diagnosis and treatment. For those who wish to pursue the subject further, the author has given as footnotes one hundred and thirty-nine pertinent references. This small volume should prove useful to the practicing physician.

Skin Diseases in Children By George M. MacKee, M.D., and Anthony C. Cipollaro, M.D. 8°, cloth, 448 pp., with 225 illustrations. New York: Paul B. Hoeber, Incorporated, 1946. \$7.50.

Skin diseases in children are extremely interesting and often present entirely different pictures from those caused by the same cutaneous disturbances in adults. The need of such a book as this is evidenced by the popularity of the first edition. The book is well written, and the print is excellent; the illustrations are numerous, depicting quite well the entities represented. There are several noteworthy chapters, especially those on allergic dermatoses, contagious diseases and syphilis. Certain other chapters, such as the one dealing with vesicular and bullous diseases, are lacking in the completeness expected in a book of this type, since the diseases discussed are fairly frequent in infants and children. It is a valuable reference book for the student, general practitioner and pediatrician.

The Diagnosis of Nervous Diseases By Sir James Purves-Stewart, K.C.M.G., C.B., Knight of St. John of Jerusalem, M.D. (Edin.), F.R.C.P. Ninth edition. 8°, cloth, 880 pp., with 358 illustrations. Baltimore: The Williams and Wilkins Company, 1945. \$11.00.

The ninth edition of this widely read book contains a considerable number of changes, but not so many as the author originally planned. He came to this country to evaluate American neurology during the war, and much of the text was revised with the aid of friends during his visit. New illustrations were furnished to replace some of the old, and the book was completely re-edited. Unfortunately, all this labor ended in disaster, for the new illustrations and fresh references, along with some of the text, were sunk in the mid-Atlantic by enemy action. The author was on another ship and therefore escaped. In spite of this setback, which might well have overwhelmed a less formidable person, the author made a further revision after returning to England, which resulted in the present text. There are enough changes to justify a new edition, and this volume will be widely welcomed by neurologists and medical students. It can be strongly recommended as in the past and is a welcome addition to the neurologic literature of the present day.

Gastro-Enterology Volume III *The liver, biliary tract and pancreas, and secondary gastro-intestinal disorders* By Henry L. Bockus, M.D., and colleagues. 8°, cloth, 1091 pp., with 427 illustrations. Philadelphia and London: W. B. Saunders Company, 1946. \$11.00.

This is a valuable book, half of which was written by Dr. Bockus and half by his colleagues in the faculty of the University of Pennsylvania Graduate School of Medicine, as in the two previous volumes. The style is pleasant, the book is well printed and bound, is accurate and complete and is beautifully and copiously illustrated. At the beginning of each chapter there is an index of contents, and a well chosen list of references is supplied at the end. About seven hundred pages are given to diseases of the liver and gall bladder, one hundred and twenty-five to diseases of the pancreas, sixty to gastro-intestinal parasites and one hundred to secondary affections of the gastrointestinal tract. This volume is especially welcome because of the recent increase in the frequency of diseases of the liver and of recent improvements in methods of diagnosis and treatment.

The material is so varied and extensive that it is difficult to single out special chapters for review. Many controversial subjects are treated with skill and good judgment, such as medical duodenal drainage, the medical treatment of gall-bladder disease, the question of early or late operation in the acute gall bladder, dyskinesia of the gall bladder, the surgery of so-called "silent gallstones," visceroptosis and the diagnosis and treatment of food allergy.

The complex physiology of the liver is described in clear and simple terms. Twenty-five liver-function tests are described, some of which are expensive and technically difficult, whereas only five or six of the simple tests are in routine daily use in most clinics. Possibly, the inclusion of so many tests that are only occasionally used may be confusing to the practitioner. Aspiration biopsy of the liver is described in half a page, this might be enlarged and a simple technique given, owing to its recent increasing use.

A large number of data on infective hepatitis and its epidemiology, transmission, pathology, early detection, diagnosis and prognosis are now becoming available from intensive study of the vast epidemics of World War II and will supplement and change the present chapters on acute hepatitis. Acute infectious hepatitis and acute yellow atrophy of the liver are described in separate chapters as different diseases, as in previous textbooks, but there is much recent evidence that they are simply different degrees of severity of the same disease.

The technical details of the treatment of patients with serious liver disease by carbohydrates, proteins and amino acids could be much improved both in acute hepatitis and in cirrhosis. Plasma transfusion, with its 5 or 6 per cent of protein, with a few grams of methionine a day, does not go far in restoring body protein reserves.

Lyons's biliary drainage is fully described, and a conservative estimate given of its value in diagnosis. Its use in treatment is not advised except in chronic infective cholangitis.

Biliary dyskinesia has been much discussed of late, and it is refreshing to find the statement, "As a working clinical diagnosis it should have a most insignificant place. We have been unable in a single instance to agree upon the diagnosis of biliary dyskinesia [in patients who have not been operated upon]."

In diseases of the pancreas the value of laboratory tests in the diagnosis of acute cases and the difficulties in chronic cases are pointed out.

There is an excellent short chapter on splenomegaly and its relation to diseases of the liver, heart and portal vein infections, hemolytic and other anemias, Hodgkin's disease, leukemia and so forth.

The chapter on functional diseases of the gastrointestinal tract is written by a neuropsychologist, and is much better than the usual chapter on these subjects. The value of psychologic and hygienic treatment is stressed in preference to drugs and placebos.

The book closes with a discussion of food poisoning of various kinds.

The work as a whole is excellent, and is highly recommended both to the specialist and as a reference book for the general practitioner.

Asclepius. A collection and interpretation of the testimonies By Emma J. Edelstein and Ludwig Edelstein. Volume I. 4°, cloth, 470 pp. Volume II. 4°, cloth, 277 pp. Baltimore: Johns Hopkins Press, 1945. \$7.50 (two volumes).

Asclepius in antiquity was the main representative of divine healing, — an important form of ancient medical treatment never opposed by ancient physicians, — and his worship played such a part in the final stage of paganism that he was judged the foremost antagonist of Christ above all other genuinely Greek gods. This work is devoted to a discussion of both aspects of the subject: Asclepius as the god of medicine and the Savior.
